Gastrointestinal disorders are commonly associated with common variable immunodeficiency, and a sprue-like syndrome, with diarrhea, steatorrhea, malabsorption, protein-losing enteropathy, and hepatosplenomegaly, may develop in patients. Paradoxically, there is an increased incidence of autoimmune disease (20%), although patients may not display the usual serologic markers. Autoimmune cytopenias are most common, but autoimmune endocrinopathies, seronegative rheumatic disease, and gastrointestinal disorders are also commonly seen. Lymph nodes may be enlarged in these patients, yet biopsies show marked reduction in plasma cells. Noncaseating granulomas are frequently found in the spleen, liver, lungs, or skin. There is an increased propensity for the development of B cell neoplasms (50- to 400-fold increase risk of lymphoma), gastric carcinomas, and skin cancers.

#### B. Laboratory Findings

The pattern of immunoglobulin isotype deficiency is variable. Most patients present with significantly depressed IgG levels, but over time all antibody classes (IgG, IgA, and IgM) may be affected. Diagnosis is confirmed in patients

---

**References**

with recurrent infections by demonstration of functional or quantitative defects in antibody production. Serum IgG levels are usually < 250 mg/dL; serum IgA and IgM levels are also subnormal. Decreased to absent functional antibody responses to protein antigen immunizations establish the diagnosis.

The causes of the panhypogammaglobulinemia in common variable immunodeficiency patients include intrinsic B cell defects that prevent terminal maturation into antibody-secreting plasma cells. The absolute B cell count in the peripheral blood in most patients, despite the underlying cellular defect, is normal. A subset of these patients have concomitant T cell immunodeficiency with increased numbers of activated CD8 cells, splenomegaly, and decreased delayed-type hypersensitivity.

**Treatment**

Patients may be treated aggressively with antibiotics at the first sign of infection. Since antibody deficiency predisposes patients to high-risk pyogenic infections, antibiotic coverage should be sure to cover encapsulated bacteria. Only after the development of bronchiectasis or after sinus surgery do patients become significantly affected by more virulent organisms such as *S. aureus* or *P. aeruginosa*. Maintenance intravenous immune globulin therapy is indicated, with infusions of 300–500 mg/kg of intravenous immune globulin given at about monthly intervals. Adjustment of dosage or of the infusion interval is made on the basis of clinical responses and steady-state trough serum IgG levels. Such therapy is effective in decreasing the incidence of potentially life-threatening infections and increasing quality of life. The yearly cost of monthly infusions can be in excess of $20,000–$30,000.

ASSESSMENT OF THE PATIENT

The diagnosis and treatment of fluid and electrolyte disorders are based on (1) careful history, (2) physical examination and assessment of total body water and its distribution, (3) serum electrolyte concentrations, (4) urine electrolyte concentrations, and (5) serum osmolality. The pathophysiology of electrolyte disorders is rooted in basic principles of total body water and its distribution across fluid compartments.

A. Body Water and Fluid Distribution

Total body water is different in men than in women, and it decreases with aging (Table 21–1). Approximately 50-60% of total body weight is water; two-thirds (40% of body weight) is intracellular, while one-third (20% of body weight) is extracellular. One-fourth of extracellular fluid (5% of body weight) is intravascular. Water may be lost from either or both compartments (intracellular and extracellular). Changes in total body water content are best evaluated by documenting changes in body weight. Effective circulating volume may be assessed by physical examination (eg, blood pressure, pulse, jugular venous distention). Quantitative measurements of effective circulating volume and intravascular volume may be invasive (ie, central venous pressure or pulmonary wedge pressure) or non-invasive (ie, inferior vena cava diameter and right atrial pressure by echocardiography) but still require careful interpretation.

B. Serum Electrolytes

The cause of electrolyte disorders may be determined by reviewing the history, underlying diseases, and medications.

C. Evaluation of Urine

The urine concentration of an electrolyte indicates renal handling of the electrolyte and whether the kidney is appropriately excreting or retaining the electrolyte. A 24-hour urine collection for daily electrolyte excretion is the gold standard for renal electrolyte handling, but it is slow and onerous. A more convenient method is the fractional excretion (Fe) of an electrolyte X (Fr_X) calculated from a spot urine sample:

\[ \text{Fr}_X(\%) = \frac{\text{Urine } X / \text{Serum } X}{\text{Urine } \text{Cr} / \text{Serum } \text{Cr}} \times 100 \]

A low fractional excretion indicates renal reabsorption (high avidity or electrolyte retention), while a high fractional excretion indicates renal wasting (low avidity or electrolyte excretion). Thus, the fractional excretion helps the clinician determine whether the kidney’s response is appropriate for a specific electrolyte disorder.

D. Serum Osmolality

Solute concentration is measured by osmolality. Osmoles per kilogram of water is osmolality; osmoles per liter of solution is osmolarity. At physiological solute concentrations (normally 285–295 mosm/kg), the two measurements are clinically interchangeable. Tonicity refers to osmolytes that are impermeable to cell membranes. Differences in osmolyte concentration across cell membranes lead to osmosis and fluid shifts, stimulation of thirst, and secretion of antidiuretic hormone (ADH). Substances that easily permeate cell membranes (eg, urea, ethanol) are ineffective osmolytes that do not cause fluid shifts across fluid compartments.

Serum osmolality can be estimated from the following formula:

\[ \text{Osmolality} = \frac{2(\text{Na}^+ \text{ mEq/L}) + \text{Glucose mg/dL}}{18} + \frac{\text{BUN mg/dL}}{2.8} \]

(1 mosm/L of glucose equals 180 mg/L and 1 mosm/L of urea nitrogen equals 28 mg/L). Sodium is the major extracellular cation; doubling the serum sodium in the formula for estimated osmolality accounts for counterbalancing anions. A discrepancy between measured and estimated osmolality of > 10 mosm/kg suggests an osmol gap, which is the presence of other unmeasured osmoles such as ethanol, methanol, isopropanol, and ethylene glycol (see Table 38–5).
Hyponatremia is defined as a serum sodium concentration < 135 mEq/L. It is the most common electrolyte abnormality in hospitalized patients. The clinician should be wary about hyponatremia since mismanagement can result in neurologic catastrophes from cerebral osmotic demyelination. Indeed, iatrogenic complications from aggressive or inappropriate therapy can be more harmful than hyponatremia itself.

A common misperception is that the sodium concentration is a reflection of total body sodium or total body water. In fact, total body water and sodium can be low, normal, or high in hyponatremia since the kidney can regulate sodium and water homeostasis independently. Most cases of hyponatremia reflect water imbalance and abnormal water handling, not sodium imbalance, indicating the primary role of ADH in the pathophysiology of hyponatremia. A diagnostic algorithm using serum osmolality and volume status separates the causes of hyponatremia into therapeutically useful categories (Figure 21–1).

**Etiology**

**A. Isotonic & Hypertonic Hyponatremia**

Serum osmolality identifies isotonic and hypertonic hyponatremia, although these cases can often be identified by careful history or previous laboratory tests.
Isotonic hyponatremia is seen with severe hyperlipidemia and hyperproteinaemia. Lipids (including chylomicrons, triglycerides, and cholesterol) and proteins (> 10 g/dL, eg, paraproteinaemias and intravenous immunoglobulin therapy) interfere with the measurement of serum sodium, causing pseudohyponatremia. Serum osmolality is isotonic because lipids and proteins do not affect osmolality measurement. Newer sodium assays using ion-specific electrodes will not produce pseudohyponatremia.

Hypertonic hyponatremia occurs with hyperglycemia and mannitol administration for increased intracranial pressure. Glucose and mannitol osmotically pull intracellular water into the extracellular space. The translocation of water lowers the serum sodium concentration. Translocational hyponatremia is not pseudohyponatremia or an artifact of sodium measurement. The sodium concentration falls 2 mEq/L for every 100 mg/dL (or 5.56 mmol/L) rise in glucose when the glucose concentration is between 200 mg/dL and 400 mg/dL (11.1 mmol/L and 22.2 mmol/L). If the glucose concentration is > 400 mg/dL, the sodium concentration falls 4 mEq/L for every 100 mg/dL rise in glucose. There is some controversy about the correction factor for the serum sodium in the presence of hyperglycemia. Many guidelines recommend a correction factor, whereby the serum sodium concentration decreases by 1.6 mEq/L for every 100 mg/dL (5.56 mmol/L) rise in plasma glucose above normal, but there is evidence that the decrease may be greater when patients have more severe hyperglycemia (> 400 mg/dL or 22.2 mmol/L) or volume depletion, or both. One group has suggested (based on short-term exposure of normal volunteers to markedly elevated glucose levels) that when the serum glucose is > 200 mg/dL, the serum sodium concentration decreases by at least 2.4 mEq/L.

B. Hypotonic Hyponatremia

Most cases of hyponatremia are hypotonic, highlighting sodium’s role as the predominant extracellular osmole. The next step is classifying hypotonic cases by the patient’s volume status.

1. Hypovolemic hypotonic hyponatremia—Hypovolemic hyponatremia occurs with renal or extrarenal volume loss and hypotonic fluid replacement (Figure 21–1). Total body sodium and total body water are decreased. To maintain intravascular volume, the pituitary increases ADH secretion, causing free water retention from hypotonic fluid replacement. The body sacrifices serum osmolality to preserve intravascular volume. In short, losses of water and salt are replaced by water alone. Without ongoing hypotonic fluid intake, the renal or extrarenal volume loss would produce hypovolemic hyponatremia.

Cerebral salt wasting is a distinct and rare subset of hypovolemic hyponatremia seen in patients with intracranial disease (eg, infections, cerebrovascular accidents, tumors, and neurosurgery). Clinical features include refractory hypovolemia and hypotension, often requiring continuous infusion of isotonic or hypertonic saline and ICU monitoring. The exact pathophysiology is unclear but includes renal sodium wasting possibly through brain natriuretic peptide, ADH release, and decreased aldosterone secretion.

2. Euvolemic hypotonic hyponatremia—Euvolemic hyponatremia has the broadest differential diagnosis. Most processes are mediated directly or indirectly through ADH, including hypothyroidism, adrenal insufficiency, medications, and the syndrome of inappropriate ADH (SIADH). The exceptions are primary polydipsia, beer potomania, and reset osmostat.

A. Hormonal abnormalities—Hypothyroidism and adrenal insufficiency can cause hyponatremia. Exactly how hypothyroidism induces hyponatremia is unclear but may be related to ADH. Adrenal insufficiency may be associated with the hyperkalemia and metabolic acidosis of hypoaldosteronism. Cortisol provides feedback inhibition for ADH release.

B. Thiazide diuretics and other medications—Thiazides induce hyponatremia typically in older female patients within days of initiating therapy. The mechanism appears to be a combination of mild diuretic-induced volume contraction, ADH effect, and intact urinary concentrating ability resulting in water retention and hyponatremia. Loop diuretics do not cause hyponatremia as frequently because of disrupted medullary concentrating gradient and impaired urine concentration.

Nonsteroidal anti-inflammatory drugs (NSAIDs) increase ADH by inhibiting prostaglandin formation. Prostaglandins and selective serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, and citalopram) can cause hyponatremia, especially in geriatric patients. Enhanced secretion or action of ADH may result from increased serotonergic tone. Angiotensin-converting enzyme (ACE) inhibitors do not block the conversion of angiotensin I to angiotensin II in the brain. Angiotensin II stimulates thirst and ADH secretion. Hyponatremia during amiodarone-loading has been reported; it usually improves with dose reduction.

Abuse of 3,4-methylenedioxymethamphetamine (MDMA, also known as Ecstasy) can lead to hyponatremia and severe neurologic symptoms, including seizures, cerebral edema, and brainstem herniation. MDMA and its metabolites increase ADH release from the hypothalamus. Primary polydipsia may contribute to hyponatremia since MDMA users typically increase fluid intake to prevent hyperthermia.

C. Nausea, pain, surgery, and medical procedures—Nausea and pain are potent stimulators of ADH release. Severe hyponatremia can develop after elective surgery in healthy patients, especially premenopausal women. Hypotonic fluids in the setting of elevated ADH levels can produce severe, life-threatening hyponatremia. Medical procedures such as colonoscopy have also been associated with hyponatremia.

D. HIV infection—Hyponatremia is seen in up to 50% of hospitalized HIV patients and 20% of ambulatory HIV patients. The differential diagnosis is broad: medication effect, adrenal insufficiency, hypoaldosteronism, central nervous system or pulmonary disease, SIADH, malignancy, and volume depletion.
E. Endurance exercise hyponatremia—Hyponatremia after endurance exercise (e.g., triathlon events and marathons) may be caused by a combination of excessive hypotonic fluid intake and continued ADH secretion. Reperfusion of the exercise-induced ischemic splanchnic bed causes delayed absorption of excessive quantities of hypotonic fluid ingested during exercise. Sustained elevation of ADH prevents water excretion in this setting. Current guidelines suggest that endurance athletes drink water according to thirst rather than to specified hourly rates of fluid intake.

F. Syndrome of inappropriate antidiuretic hormone secretion—Under normal circumstances, hypovolemia and hyperosmolality stimulate ADH secretion. ADH release is inappropriate without these physiological cues. Normal regulation of ADH release occurs from both the central nervous system and the chest via baroreceptors and neural input. The major causes of SIADH (Table 21–2) are disorders affecting the central nervous system (structural, metabolic, psychiatric, or pharmacologic processes) or the lungs (infectious, mechanical, oncologic). Medications commonly cause SIADH by increasing ADH or its action. Some carcinomas, especially small cell lung carcinoma, can autonomously secrete ADH.

G. Psychogenic polydipsia and beer potomania—Marked free water intake (generally > 10 L/d) may produce hyponatremia. Euvolemia is maintained through renal excretion of sodium. Urine sodium is therefore generally elevated (> 20 mEq/L), and ADH levels are appropriately suppressed. As the increased free water is excreted, the urine osmolality approaches the minimum of 50 mosm/kg. Polydipsia occurs in psychiatric patients. Psychiatric medications may interfere with water excretion or increase thirst through anticholinergic side effects, further increasing water intake. The hyponatremia of beer potomania occurs in patients who consume large amounts of beer. Free water excretion is decreased because of decreased solute consumption and production; muscle wasting and malnutrition are contributing factors. Without enough solute, these patients have decreased free water excretory capacity even if they maximally dilute the urine.

H. Reset osmostat—Reset osmostat is a rare cause of hyponatremia characterized by appropriate ADH regulation in response to water deprivation and fluid challenges. Patients with reset osmostat regulate serum sodium and serum osmolality around a lower set point, concentrating or diluting urine in response to hyperosmolality and hypo-osmolality. The mild hypo-osmolality of pregnancy is a form of reset osmostat.

3. Hypervolemic hypotonic hyponatremia—Hypervolemic hyponatremia occurs in the edematous states of cirrhosis, heart failure, nephrotic syndrome, and advanced kidney disease (Figure 21–1). In cirrhosis and heart failure, effective circulating volume is decreased due to peripheral vasodilation or decreased cardiac output. Increased renin-angiotensin-aldosterone system activity and ADH secretion result in water retention. Note the pathophysiological similarity to hypovolemic hyponatremia—the body sacrifices osmolality in an attempt to restore effective circulating volume.

The pathophysiology of hyponatremia in nephrotic syndrome is not completely understood, but the primary disturbance may be renal sodium retention, resulting in overfilling of the intravascular space and secondary edema.
formation as fluid enters the interstitial space. Previously, it was thought that the decreased oncotnic pressure of hypoalbuminemia caused fluid shifts from the intravascular space to the interstitial compartment. Intravascular underfilling led to secondary renal sodium retention. However, patients receiving therapy for glomerular disease and nephrotic syndrome often have edema resolution prior to normalization of the serum albumin.

Patients with advanced kidney disease typically have sodium retention and decreased free water excretory capacity, resulting in hypervolemic hyponatremia.

Clinical Findings

A. Symptoms and Signs

Whether hyponatremia is symptomatic depends on its severity and acuity. Chronic disease can be severe (sodium concentration < 110 mEq/L), yet remarkably asymptomatic because the brain has adapted by decreasing its tonicity over weeks to months. Acute disease that has developed over hours to days can be severely symptomatic with relatively modest hyponatremia. Mild hyponatremia (sodium concentrations of 130–135 mEq/L) is usually asymptomatic.

Mild symptoms of nausea and malaise progress to headache, lethargy, and disorientation as the sodium concentration drops. The most serious symptoms are respiratory arrest, seizure, coma, permanent brain damage, brainstem herniation, and death. Premenopausal women are much more likely than menopausal women to die or suffer permanent brain injury from hyponatremic encephalopathy, suggesting a hormonal role in the pathophysiology.

Evaluation starts with a careful history for new medications, changes in fluid intake (polydipsia, anorexia, intravenous fluid rates and composition), fluid output (nausea and vomiting, diarrhea, ostomy output, polyuria, oliguria, insensible losses). The physical examination should help categorize the patient’s volume status into hypovolemia, euvolemia, or hypervolemia.

B. Laboratory Findings

Laboratory assessment should include serum electrolytes, serum creatinine, serum osmolality, and urine sodium. The etiology of most cases of hyponatremia will be apparent from the history, physical, and basic laboratory tests. Additional tests of thyroid and adrenal function will occasionally be necessary.

SIADH is a clinical diagnosis characterized by (1) hyponatremia; (2) decreased osmolality (< 280 mosm/kg); (3) absence of heart, kidney, or liver disease; (4) normal thyroid and adrenal function (see Chapter 26); and (5) urine sodium usually over 20 mEq/L. In clinical practice, ADH levels are not measured. Patients with SIADH may have low blood urea nitrogen (BUN) (< 10 mg/dL [or < 3.6 mmol/L]) and hypouricemia (< 4 mg/dL [or < 238 mcmol/L]), which are not only dilutional but result from increased urea and uric acid clearances in response to the volume-expanded state. Azotemia may reflect volume contraction, ruling out SIADH, which is seen in euvolemic patients.

Complications

The most serious complication of hyponatremia is iatrogenic cerebral osmotic demyelination from overly rapid sodium correction. Also called central pontine myelinolysis, cerebral osmotic demyelination may occur outside the brainstem. Demyelination may occur days after sodium correction or initial neurologic recovery from hyponatremia. Hypoxic episodes during hyponatremia may contribute to demyelination. The neurologic effects are generally catastrophic and irreversible.

Treatment

Regardless of the patient’s volume status, another common feature is to restrict free water and hypotonic fluid intake, since these solutions will exacerbate hyponatremia. Free water intake from oral intake and intravenous fluids should generally be < 1–1.5 L/d.

Hypovolemic patients require adequate fluid resuscitation from isotonic fluids (either normal saline or lactated Ringer solution) to suppress the hypovolemic stimulus for ADH release. Patients with cerebral salt wasting may require hypertonic saline to prevent circulatory collapse; some may respond to fludrocortisone. Hypervolemic patients may require loop diuretics or dialysis, or both, to correct increased total body water and sodium. Euvolemic patients may respond to free water restriction alone.

Pseudohyponatremia from hypertriglyceridemia or hyperproteinemia requires no therapy except confirmation with the clinical laboratory. Translocational hyponatremia from glucose or mannitol can be managed with glucose correction or mannitol discontinuation (if possible). No specific therapy is necessary in patients with reset osmostat since they successfully regulate their serum sodium with fluid challenges and water deprivation.

Symptomatic and severe hyponatremia generally require hospitalization for careful monitoring of fluid balance and weights, treatment, and frequent sodium checks. Inciting medications should be discontinued if possible.

There is no consensus about the optimal rate of sodium correction in symptomatic hyponatremic patients. A reasonable rate is 10–12 mEq/L/d in mildly to moderately symptomatic patients. A more aggressive rate of 1–1.5 mEq/L/h (to a maximum correction of 10–12 mEq/L) has been used in severely symptomatic patients. Sodium concentration should be monitored as frequently as every 1–2 hours. As symptoms improve or resolve, the correction rate should be reduced to roughly 0.5 mEq/L/h. To avoid overcorrection, the clinician should stabilize the sodium around 125 mEq/L to 130 mEq/L.

In severely symptomatic patients, the clinician should calculate the sodium deficit and deliver 3% hypertonic saline. The sodium deficit can be calculated by the following formula:

\[ \text{Sodium deficit} = \text{Total body water (TBW)} \times (\text{Desired serum Na–Actual serum Na}) \]

where TBW is typically 50% of total mass in women and 55% of total mass in men. For example, a nonedematous, severely symptomatic 70 kg woman with a serum sodium
of 122 mEq/L should have her serum sodium corrected to approximately 132 mEq/L in the first 24 hours. Her sodium deficit is calculated as:

\[
\text{Sodium deficit} = 70 \text{ kg} \times 0.5 \times (132 \text{ mEq/L} - 122 \text{ mEq/L}) = 350 \text{ mEq}
\]

3% hypertonic saline has a sodium concentration of 514 mEq/1000 mL. The delivery rate for hypertonic saline can be calculated as:

\[
\text{Delivery rate} = \frac{\text{Sodium deficit}}{514 \text{ mEq/1000 mL}} \times \frac{24 \text{ hours}}{24 \text{ hours}} = 28 \text{ mL/hour}
\]

In general, the 3% hypertonic saline infusion rate should not exceed 0.5 mL/kg body weight/h; higher rates may represent a miscalculated sodium deficit or a mathematical error. The goal is not to correct the serum sodium by more than 10–12 mEq/L over the first 24 hours. Hypertonic saline in hypervolemic patients can be hazardous, resulting in worsening volume overload, pulmonary edema, and ascites.

For patients who cannot adequately restrict free water or have an inadequate response to conservative measures, demeclocycline (300–600 mg orally twice daily) inhibits the effect of ADH on the distal tubule. Onset of action may require 1 week, and urinary concentrating ability may be permanently impaired, resulting in nephrogenic diabetes insipidus (DI) and even hypernatremia. Cirrhosis may increase the nephrotoxicity of demeclocycline.

\textbf{Vasopressin antagonists} may revolutionize the treatment of euvolemic and hypervolemic hyponatremia, especially in heart failure. Lixivaptan, tolvaptan, and satavaptan are oral selective vasopressin-2 receptor antagonists. V2 receptors mediate the diuretic effect of ADH. For hospitalized patients with euvolemic SIADH, conivaptan is given as an intravenous loading dose of 20 mg delivered over 30 minutes, then as 20 mg continuously over 24 hours. Subsequent infusions may be administered every 1–3 days at 20–40 mg/d by continuous infusion. Tolvaptan and conivaptan are available in the United States. (Lixivaptan and satavaptan are not yet approved by the Food and Drug Administration [FDA] for use in the United States.)

\textbf{When to Refer}

- Nephrology or endocrinology consultation should be considered in severe, symptomatic, refractory, or complicated cases of hyponatremia.
- Aggressive therapies with hypertonic saline, demeclocycline, vasopressin antagonists, or dialysis mandate specialist consultation.
- Consultation may be necessary with end-stage liver or heart disease.

\textbf{When to Admit}

Hospital admission is necessary for symptomatic patients or those requiring aggressive therapies for close monitoring and frequent laboratory testing.
A. Nonrenal losses—Hypernatremia will develop if water intake falls behind hypotonic fluid losses from excessive sweating, the respiratory tract, or bowel movements. Lactulose causes an osmotic diarrhea with loss of free water.

B. Renal losses—While severe hyperglycemia can cause translocational hyponatremia (see above), progressive volume depletion from glucosuria can result in hypernatremia. Osmotic diuresis can occur with the use of mannitol or urea.

2. Urine osmolality < 250 mosm/kg—Hypernatremia with a dilute urine (osmolality < 250 mosm/kg) is characteristic of DI. Central DI results from inadequate ADH release. Nephrogenic DI results from renal insensitivity to ADH; common causes include lithium, demeclocycline, relief of urinary obstruction, interstitial nephritis, hypercalcemia, and hypokalemia.

Treatment

Treatment of hypernatremia includes correcting the cause of the fluid loss, replacing water, and replacing electrolytes (as needed). In response to increases in plasma osmolality, brain cells synthesize solutes called idiosyncratic osmoles, which cause intracellular fluid shifts. Osmole production begins 4–6 hours after dehydration and takes several days to reach steady state. If hypernatremia is rapidly corrected, the osmotic imbalance may cause cerebral edema and potentially severe neurologic impairment. Fluids should be administered over a 48-hour period, aiming for serum sodium correction of approximately 1 mEq/L/h (1 mmol/L/h). There is no consensus about the optimal rates of sodium correction in hypernatremia and hyponatremia.

A. Choice of Type of Fluid for Replacement

1. Hypernatremia with hypovolemia—Hypovolemic patients should receive isotonic 0.9% normal saline to restore euvolemia and to treat hyperosmolality, since isotonic 0.9% normal saline (308 mosm/kg) is often hypo-osmolar compared with plasma. After adequate volume resuscitation with normal saline, 0.45% saline or 5% dextrose (or both) can be used to replace any remaining free water deficit. Milder volume deficits may be treated with 0.45% saline and 5% dextrose.

2. Hypernatremia with euvolemia—Water ingestion or intravenous 5% dextrose will result in the excretion of excess sodium in the urine. If the glomerular filtration rate (GFR) is decreased, diuretics will increase urinary sodium excretion but may impair renal concentrating ability, increasing the quantity of water that needs to be replaced.

3. Hypernatremia with hypervolemia—Treatment includes 5% dextrose solution to reduce hyperosmolality. Loop diuretics may be necessary to promote natriuresis and lower total body sodium. In severe rare cases with kidney disease, hemodialysis may be necessary to correct the excess total body sodium and water.

B. Calculation of Water Deficit

Fluid replacement should include the free water deficit and additional maintenance fluid to replace ongoing and anticipated fluid losses.

1. Acute hypernatremia—In acute dehydration without much solute loss, free water loss is similar to the weight loss. Initially, a 5% dextrose solution may be used. As correction of water deficit progresses, therapy should continue with 0.45% saline with dextrose.

2. Chronic hypernatremia—The water deficit is calculated to restore normal sodium concentration, typically 140 mEq/L. Total body water (TBW) (Table 21–1) correlates with muscle mass and therefore decreases with advancing age, cachexia, and dehydration and is lower in women than in men. Current TBW equals 40–60% current body weight.

\[
\text{Volume (in L) = Current TBW} \times \frac{140}{[\text{Na}^+] - 140} \text{to be replaced}
\]

When to Refer

Patients with refractory or unexplained hypernatremia should be referred for subspecialist consultation.

When to Admit

- Patients with symptomatic hypernatremia require hospitalization for evaluation and treatment.
- Significant comorbidities or concomitant acute illnesses, especially if contributing to hypernatremia, may necessitate hospitalization.

The hallmark of a volume overloaded state is sodium retention. Abnormally low arterial filling, such as from congestive heart failure or cirrhosis, activates the neurohumoral axis, which stimulates the renin-angiotensin–aldosterone system, the sympathetic nervous system, and ADH (vasopressin) release. Sodium retention with edema results. The stimulus for vasopressin release is nonosmotic. Released in response to baroreceptor activation, vasopressin stimulates renal V₂ receptors, resulting in water reabsorption, edema formation, and hyponatremia.

**HYPEROSMOLALITY WITH TRANSIENT OR NO SIGNIFICANT SHIFT IN WATER**

Urea and alcohol readily cross cell membranes and can produce hyperosmolality. Urea is an ineffective osmole with little effect on osmotic water movement across cell membranes. Alcohol quickly equilibrates between the intra–cellular and extracellular compartments, adding 22 mosmol/L for every 100 mg/dL (or 21.7 mmol/L) of ethanol. Ethanol ingestion should be considered in any case of stupor or coma with an elevated osmol gap (measured osmolality – calculated osmolality > 10 mosmol/kg). Other toxic alcohols such as methanol and ethylene glycol cause an osmol gap and a metabolic acidosis with an increased anion gap (see Chapter 38). The combination of an increased anion gap metabolic acidosis and an osmol gap exceeding 10 mosmol/kg is not specific for toxic alcohol ingestion and may occur with alcoholic ketoacidosis or lactic acidosis (see Metabolic Acidosis).

**HYPEROSMOLALITY ASSOCIATED WITH SIGNIFICANT SHIFTS IN WATER**

Increased concentrations of solutes that do not readily enter cells cause a shift of water from intracellular to extracellular. Hyperosmolality of effective osmoles such as sodium and glucose causes symptoms, primarily neurologic. The severity of symptoms depends on the degree of hyperosmolality and rapidity of development. In acute hyperosmolality, somnolence and confusion can appear when the osmolality exceeds 320–330 mosmol/kg; coma, respiratory arrest, and death can result when osmolality exceeds 340–350 mosmol/kg.

and blocked by $\alpha$-adrenergic stimulation. Aldosterone is an important regulator of total body potassium, increasing potassium secretion in the distal renal tubule. The most common cause of hypokalemia, especially in developing countries, is gastrointestinal loss from infectious diarrhea. The potassium concentration in intestinal secretion is ten times higher (80 mEq/L) than in gastric secretions. Hypokalemia in the presence of acidosis suggests profound potassium depletion and requires urgent treatment. Self-limited hypokalemia occurs in 50–60% of trauma patients, perhaps related to enhanced release of epinephrine.

Hypokalemia increases the likelihood of digitalis toxicity. In patients with heart disease, hypokalemia induced by $\beta_2$-adrenergic agonists and diuretics may substantially increase the risk of arrhythmias. Numerous genetic mutations affect fluid and electrolyte metabolism, including disorders of potassium metabolism (Table 21–4).

Magnesium is an important cofactor for potassium uptake and maintenance of intracellular potassium levels. Loop diuretics (eg, furosemide) cause substantial renal potassium and magnesium losses. Magnesium depletion should be considered in refractory hypokalemia.

### Clinical Findings

#### A. Symptoms and Signs

Muscular weakness, fatigue, and muscle cramps are frequent complaints in mild to moderate hypokalemia. Gastrointestinal smooth muscle involvement may result in constipation or ileus. Flaccid paralysis, hyporeflexia, hypercapnia, tetany, and rhabdomyolysis may be seen with severe hypokalemia (< 2.5 mEq/L). The presence of hypertension may be a clue to the diagnosis of hypokalemia from aldosterone or mineralocorticoid excess (Table 21–4). Renal manifestations include nephrogenic DI and interstitial nephritis.

#### B. Laboratory Findings

Urinary potassium concentration is low (< 20 mEq/L) as a result of extrarenal loss (eg, diarrhea, vomiting) and inappropriately high (> 40 mEq/L) with renal loss (eg, mineralocorticoid excess, Bartter syndrome, Liddle syndrome) (Table 21–3).

The transtubular [K+] gradient (TTKG) is a simple and rapid evaluation of net potassium secretion. TTKG is calculated as follows:

$$\text{TTKG} = \frac{\text{Urine K}^+ / \text{Plasma K}^+}{\text{Urine osm} / \text{Plasma osm}}$$

Hypokalemia with a TTKG > 4 suggests renal potassium loss with increased distal K+ secretion. In such cases, plasma renin and aldosterone levels are helpful in differential diagnosis. The presence of nonabsorbed anions, such as bicarbonate, increases the TTKG.

FGF23, fibroblast growth factor 23; RTA, renal tubular acidosis.
C. Electrocadiogram

The electrocardiogram (ECG) shows decreased amplitude and broadening of T waves, prominent U waves, premature ventricular contractions, and depressed ST segments.

▶ Treatment

Oral potassium supplementation is the safest and easiest treatment for mild to moderate deficiency. Dietary potassium is almost entirely coupled to phosphate—rather than chloride—and is therefore not effective in correcting potassium loss associated with chloride depletion from diuretics or vomiting. In the setting of abnormal kidney function and mild to moderate diuretic dosage, 20 mEq/d of oral potassium is generally sufficient to prevent hypokalemia, but 40–100 mEq/d over a period of days to weeks is needed to treat hypokalemia and fully replete potassium stores.

Intravenous potassium is indicated for patients with severe hypokalemia and for those who cannot take oral supplementation. For severe deficiency, potassium may be given through a peripheral intravenous line in a concentration up to 40 mEq/L and at rates up to 10 mEq/h. Concentrations of up to 20 mEq/h may be given through a central venous catheter. Continuous ECG monitoring is indicated, and the serum potassium level should be checked every 3–6 hours. Avoid glucose-containing fluid to prevent further shifts of potassium into the cells. Magnesium deficiency should be corrected, particularly in refractory hypokalemia.

▶ When to Refer

Patients with unexplained hypokalemia, refractory hypokalemia, or clinical features suggesting alternative diagnoses (e.g., aldosteronism or hypokalemic periodic paralysis) should be referred for endocrinology or nephrology consultation.

▶ When to Admit

Patients with symptomatic or severe hypokalemia, especially with cardiac manifestations, require cardiac monitoring, frequent laboratory testing, and potassium supplementation.

---

**Hyperkalemia**

Hyperkalemia usually occurs in patients with advanced kidney disease but can also develop with normal kidney function (Table 21–5). Acidosis causes intracellular potassium to shift extracellularly. Serum potassium concentration rises about 0.7 mEq/L for every decrease of 0.1 pH unit during acidosis. If the serum potassium concentration by 1–2 mEq/L by causing acidosis and potassium shift from cells. In the absence of acidosis, serum potassium concentration rises about 1 mEq/L when there is a total body potassium excess of 1–4 mEq/kg. However, the higher the serum potassium concentration, the smaller the excess necessary to raise the potassium levels further.

Mineralocorticoid deficiency from Addison disease or chronic kidney disease (CKD) is another cause of hyperkalemia with decreased renal excretion of potassium. Mineralocorticoid resistance due to genetic disorders, interstitial kidney disease, or urinary tract obstruction also leads to hyperkalemia.

ACE inhibitors or angiotensin-receptor blockers (ARBs), commonly used in patients with congestive heart failure or CKD, may cause hyperkalemia. The concomitant use of spironolactone, eplerenone, or β-blockers further increases the risk of hyperkalemia. Thiazide or loop diuretics and sodium bicarbonate may minimize hyperkalemia. Persistent mild hyperkalemia in the absence of ACE inhibitor or ARB therapy is usually due to type IV renal tubular acidosis (RTA). Heparin inhibits aldosterone production in the adrenal glands, causing hyperkalemia.

Trimethoprim is structurally similar to amiloride and triamterene, and all three drugs inhibit renal potassium excretion through suppression of sodium channels in the distal nephron.

Cyclosporine and tacrolimus can induce hyperkalemia in organ transplant recipients, especially kidney transplant patients, partly due to suppression of the basolateral Na+/K+-ATPase in

---

**Essentials of Diagnosis**

- Serum potassium level > 5.0 mEq/L (>5.0 mmol/L).
- Hyperkalemia may develop in patients taking ACE inhibitors, angiotensin-receptor blockers, potassium-sparing diuretics, or their combination, even with no or only mild kidney dysfunction.
- The ECG may show peaked T waves, widened QRS and biphasic QRS-T complexes, or may be normal despite life-threatening hyperkalemia.
- Measurement of plasma potassium level differentiates potassium leak from blood cells in cases of clotting, leukocytosis, and thrombocytosis from elevated serum potassium.
- Rule out extracellular potassium shift from the cells in acidosis and assess renal potassium excretion.

</table>

ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

Hyperkalemia is commonly seen in HIV patients and has been attributed to impaired renal excretion of potassium due to pentamidine or trimethoprim-sulfamethoxazole or to hyporeninemic hypoaldosteronism.

### Clinical Findings

Hyperkalemia impairs neuromuscular transmission, causing muscle weakness, flaccid paralysis, and ileus. Electrocardiography is not a sensitive method for detecting hyperkalemia, since nearly half of patients with a serum potassium level > 6.5 mEq/L will not manifest ECG changes. ECG changes in hyperkalemia include bradycardia, PR interval prolongation, peaked T waves, QRS widening, and bIPHASIC QRS–T complexes. Conduction disturbances, such as bundle branch block and atrioventricular block, may occur. Ventricular fibrillation and cardiac arrest are terminal events.

### Prevention

Inhibitors of the renin-angiotensin-aldosterone axis (ie, ACE inhibitors, ARBs, and spironolactone) and potassium-sparing diuretics (eplerenone, triamterene) should be used cautiously in patients with heart failure, liver failure, and kidney disease. Laboratory monitoring should be performed within 1 week of drug initiation or dosage increase.

### Treatment

The diagnosis should be confirmed by repeat laboratory testing to rule out spurious hyperkalemia, especially in the absence of medications that cause hyperkalemia or in patients without kidney disease or a previous history of hyperkalemia. Plasma potassium concentration can be measured to avoid hyperkalemia due to potassium leakage out of red cells, white cells, and platelets. Kidney dysfunction should be ruled out at the initial assessment.

Treatment consists of withholding exogenous potassium, identifying the cause, reviewing the patient’s medications and dietary potassium intake, and correcting the hyperkalemia. Emergent treatment is indicated when cardiac toxicity, muscle paralysis, or severe hyperkalemia (potassium > 6.5 mEq/L) is present, even in the absence of ECG changes. Insulin, bicarbonate, and β-agonists shift potassium intracellularly within minutes of administration (Table 21–6). Intravenous calcium may be given to antagonize the cell membrane effects of potassium, but its use should be restricted to life-threatening hyperkalemia in patients taking digitals because hypercalcemia may cause digitalis toxicity. Hemodialysis may be required to remove potassium in patients with acute or chronic kidney injury.

### When to Refer

- Patients with hyperkalemia from kidney disease and reduced renal potassium excretion should see a nephrologist.
- Transplant patients may need adjustment of their immunosuppression regimen by transplant specialists.

### When to Admit

Patients with severe hyperkalemia > 6 mEq/L, any degree of hyperkalemia associated with ECG changes, or concomitant illness (eg, tumor lysis, rhabdomyolysis, metabolic acidosis) should be sent to the emergency department for immediate treatment.

---

The calcium-sensing receptor, a transmembrane protein that detects the extracellular calcium concentration, has been identified in the parathyroid gland and the kidney. Functional defects in this protein are associated with diseases of abnormal calcium metabolism such as familial hypocalcemia and familial hypocalciuric hypercalcemia (Table 21–4).

The normal total plasma (or serum) calcium concentration is 8.5–10.5 mg/dL (or 2.1–2.6 mmol/L). Ionized calcium (normal: 4.6–5.3 mg/dL [or 1.15–1.32 mmol/L]) is physiologically active and necessary for muscle contraction and nerve function.
HYPOCALCEMIA

ESSENTIALS OF DIAGNOSIS

- Often mistaken as a neurologic disorder.
- Check for decreased parathyroid hormone (PTH), vitamin D, or magnesium depletion.
- If the ionized calcium level is normal despite a low total serum calcium, calcium metabolism is usually normal.

General Considerations

The most common cause of low total serum calcium is hypoalbuminemia. When serum albumin concentration is lower than 4 g/dL (40 g/L), serum Ca\(^{2+}\) concentration is reduced by 0.8–1 mg/dL (0.20–0.25 mmol/L) for every 1 g/dL (10 g/L) of albumin.

The most accurate measurement of serum calcium is the ionized calcium concentration. True hypocalcemia (decreased ionized calcium) implies insufficient action of PTH or active vitamin D. Important causes of hypocalcemia are listed in Table 21–7.

The most common cause of hypocalcemia is advanced CKD, in which decreased production of active vitamin D (1.25 dihydroxyvitamin D\(_3\)) and hyperphosphatemia both play a role (see Chapter 22). Some cases of primary hypoparathyroidism are due to mutations of the calcium-sensing receptor in which inappropriate suppression of PTH release leads to hypocalcemia (see Chapter 26). Magnesium depletion reduces both PTH release and tissue responsiveness to PTH, causing hypocalcemia. Hypocalcemia in pancreatitis is a marker of severe disease. Elderly hospitalized patients with hypocalcemia and hypophosphatemia, with or without an elevated PTH level, are likely vitamin D deficient.

Clinical Findings

A. Symptoms and Signs

Hypocalcemia increases excitation of nerve and muscle cells, primarily affecting the neuromuscular and cardiovascular systems. Spasm of skeletal muscle causes cramps and tetany. Laryngospasm with stridor can obstruct the airway. Convulsions, perioral and peripheral paresthesias, and abdominal pain can develop. Classic physical findings include Chvostek sign (contraction of the facial muscle in response to tapping the facial nerve) and Trousseau sign (carpal spasm occurring with occlusion of the brachial artery by a blood pressure cuff). QT prolongation predisposes to ventricular arrhythmias. In chronic hypoparathyroidism, cataracts and calcification of basal ganglia may appear (see Chapter 26).

B. Laboratory Findings

- Serum calcium concentration is low (< 8.5 mg/dL [or < 2.1 mmol/L]). In true hypocalcemia, the ionized serum calcium concentration is also low (< 4.6 mg/dL [or < 1.15 mmol/L]). Serum phosphate is usually elevated in hypoparathyroidism or in advanced CKD, whereas it is suppressed in early CKD or vitamin D deficiency.
- Serum magnesium concentration is commonly low. In respiratory alkalosis, total serum calcium is normal but ionized calcium is low. The ECG shows a prolonged QT interval.

\(^1\)Ionized calcium concentration is normal.

Treatment\(^1\)

A. Severe, Symptomatic Hypocalcemia

In the presence of tetany, arrhythmias, or seizures, intravenous calcium gluconate is indicated. Because of the short duration of action, continuous calcium infusion is usually required. Ten to 15 milligrams of calcium per kilogram body weight, or six to eight 10-mL vials of 10% calcium gluconate (558–744 mg of calcium), is added to 1 L of D\(_5\)W and infused over 4–6 hours. By monitoring the serum calcium level frequently (every 4–6 hours), the infusion rate is adjusted to maintain the serum calcium level at 7–8.5 mg/dL.

B. Asymptomatic Hypocalcemia

Oral calcium (1–2 g) and vitamin D preparations, including active vitamin D sterols, are used. Calcium carbonate is well tolerated and less expensive than many other calcium tablets. A check of urinary calcium excretion is recommended after the initiation of therapy because hypercalciuria (urine calcium excretion > 300 mg or > 7.5 mmol per day)

\(^1\)See also Chapter 26 for discussion of the treatment of hypoparathyroidism.
or urine calcium:creatinine ratio > 0.3 may impair kidney function in these patients. The low serum calcium associated with hypoalbuminemia does not require replacement therapy. If serum Mg\(^{2+}\) is low, therapy must include magnesium replacement, which by itself will usually correct hypocalcemia.

**When to Refer**

Patients with complicated hypocalcemia from hypoparathyroidism, familial hypocalcemia, or CKD require referral to an endocrinologist or nephrologist.

**When to Admit**

Patients with tetany, arrhythmias, seizures, or other symptoms of hypocalcemia require immediate evaluation and therapy.

---

**HYPERCALCEMIA**

**Essentials of Diagnosis**

- Primary hyperparathyroidism and malignancy-associated hypercalcemia are the most common causes.
- Hypercalciuria usually precedes hypercalcemia.
- Most often, asymptomatic, mild hypercalcemia (≥ 10.5 mg/dl [or 2.6 mmol/L]) is due to primary hyperparathyroidism, whereas the symptomatic, severe hypercalcemia (≥ 14 mg/dl [or 3.5 mmol/L]) is due to hypercalcemia of malignancy.

**General Considerations**

Important causes of hypercalcemia are listed in Table 21–8. Primary hyperparathyroidism and malignancy account for 90% of cases. Primary hyperparathyroidism is the most common cause of hypercalcemia (usually mild) in ambulatory patients. Chronic hypercalcemia (over 6 months) or some manifestation such as nephro lithiasis also suggests a benign cause. Tumor production of PTH-related proteins (PTHrP) is the most common paraneoplastic endocrine syndrome, accounting for most cases of hypercalcemia in inpatients (see Table 39–2). The neoplasm is clinically apparent in nearly all cases when the hypercalcemia is detected, and the prognosis is poor. Granulomatous diseases, such as sarcoidosis and tuberculosis, cause hypercalcemia via overproduction of active vitamin D\(_3\) (1,25 dihydroxyvitamin D\(_3\)).

**Increased intake or absorption**
- Milk-alkali syndrome
- Vitamin D or vitamin A excess

**Endocrine disorders**
- Primary hyperparathyroidism
- Secondary or tertiary hyperparathyroidism (usually associated with hypocalcemia)
- Acromegaly
- Adrenal insufficiency
- Pheochromocytoma
- Thyrotoxicosis

**Neoplastic diseases**
- Tumors producing PTH-related proteins (ovary, kidney, lung)
- Multiple myeloma (elaboration of osteoclast-activating factor)
- Lymphoma (occasionally from production of calcitriol)

**Miscellaneous causes**
- Thiazide diuretic use
- Granulomatous diseases (production of calcitriol)
- Paget disease of bone
- Hypophosphatemia
- Immobilization
- Familial hypocalciuric hypercalcemia
- Complications of kidney transplantation
- Lithium intake

**Clinical Findings**

**A. Symptoms and Signs**

The history and physical examination should focus on the duration of hypercalcemia and evidence for a neoplasm. Hypercalcemia may affect gastrointestinal, kidney, and neurologic function. Mild hypercalcemia is often asymptomatic. Symptoms usually occur if the serum calcium is > 12 mg/dL (or > 3 mmol/L) and tend to be more severe if hypercalcemia develops acutely. Symptoms include constipation and polyuria, except in hypertauric hypercalcemia, in which polyuria is absent. Other symptoms include nausea, vomiting, anorexia, peptic ulcer disease, renal colic, and hematuria from nephro lithiasis. Polyuria from hypercalciuria-induced nephrogenic DI can result in volume depletion and acute kidney injury. Neurologic manifestations range from mild drowsiness to weakness, depression, lethargy, stupor, and coma in severe

**PTH, parathyroid hormone.**
hypercalcemia. Ventricular ectopy and idioventricular rhythm occur and can be accentuated by digitalis.

B. Laboratory Findings

The ionized calcium exceeds 1.32 mmol/L. A high serum chloride concentration and a low serum phosphate concentration in a ratio > 33:1 (or > 102 if SI units are utilized) suggests primary hyperparathyroidism where PTH decreases proximal tubular phosphate reabsorption. A low serum chloride concentration with a high serum bicarbonate concentration, along with elevated BUN and creatinine, suggests milk-alkali syndrome. Severe hypercalcemia (> 15 mg/dL [or > 3.75 mmol/L]) generally occurs in malignancy. More than 300 mg (or > 7.3 mmol) per day of urinary calcium excretion suggests hypercalciuria; < 100 mg (or < 2.5 mmol) per day suggests hypocalciuria. Hypercalciuric patients—such as those with malignancy or those receiving oral active vitamin D therapy—may easily develop hypercalcemia in case of volume depletion. Serum phosphate may or may not be low, depending on the cause. Hypocalciuric hypercalcemia occurs in milk-alkali syndrome, thiazide diuretic use, and familial hypocalciuric hypercalcemia.

The chest radiograph may reveal malignancy or granulomatous disease. The ECG shows a shortened QT interval. Measurements of PTH and PTHrP help distinguish between hyperparathyroidism (elevated PTH) and malignancy. More than 300 mg (or > 7.3 mmol) per day suggests hypocalciuria; < 100 mg (or < 2.5 mmol) per day suggests hypocalciuria. Hypercalciuric patients—such as those with malignancy or those receiving oral active vitamin D therapy—may easily develop hypercalcemia in case of volume depletion. Serum phosphate may or may not be low, depending on the cause. Hypocalciuric hypercalcemia occurs in milk-alkali syndrome, thiazide diuretic use, and familial hypocalciuric hypercalcemia.

Until the primary cause can be identified and treated, renal excretion of calcium is promoted through aggressive hydration and forced calciuresis. The tendency in hypercalcemia is hypovolemia from nephrogenic DI. In dehydrated patients with normal cardiac and kidney function, 0.45% saline or 0.9% saline can be given rapidly (250–500 mL/h). A meta-analysis questioned the efficacy and safety profile of intravenous furosemide for hypercalcemia. Thiazides can worsen hypercalcemia.

Bisphosphonates are the treatment of choice for hypercalcemia of malignancy. Although they are safe, effective, and normalize calcium in > 70% of patients, bisphosphonates may require up to 48–72 hours before reaching full therapeutic effect. Calcitonin may be helpful in the short-term until bisphosphonates reach therapeutic levels. In emergency cases, dialysis with low calcium dialysate may be needed. The calcimimetic agent cinacalcet hydrochloride suppresses PTH secretion and decreases serum calcium concentration and holds promise as a treatment option. See Chapter 39 for a discussion of the treatment of hypercalcemia of malignancy and Chapter 26 for a discussion of the treatment of hypercalcemia of hyperparathyroidism.

Typically, if dialysis patients do not receive proper supplementation of calcium and active vitamin D, hypercalcemia and hyperphosphatemia develop. On the other hand, hypercalcemia can sometimes develop, particularly in the setting of severe secondary hyperparathyroidism, characterized by high PTH levels and subsequent release of calcium from bone. Therapy may include intravenous vitamin D, which further increases the serum calcium concentration. Another type of hypercalcemia occurs when PTH levels are low. Bone turnover is decreased, which results in a low buffering capacity for calcium. When calcium is administered in calcium-containing phosphate binders or dialysate, or when vitamin D is administered, hypercalcemia results. Hypercalcemia in dialysis patients usually occurs in the presence of hyperphosphatemia, and metastatic calcification may occur. Malignancy should be considered as a cause of the hypercalcemia.

When to Refer

- Patients may require referral to an oncologist or endocrinologist depending on the underlying cause of hypercalcemia.
- Patients with granulomatous diseases (eg, tuberculosis and other chronic infections, granulomatosis with polyangiitis [formerly Wegener granulomatosis], sarcoidosis) may require assistance from infectious disease specialists, rheumatologists, or pulmonologists.

When to Admit

- Patients with symptomatic or severe hypercalcemia require immediate treatment.
- Unexplained hypercalcemia with associated conditions, such as acute kidney injury or suspected malignancy, may require urgent treatment and expedited evaluation.

of phosphate is facilitated by active vitamin D. PTH stimulates phosphate release from bone and renal phosphate excretion; primary hyperparathyroidism can lead to hypophosphatemia and depletion of bone phosphate stores. By contrast, growth hormone augments proximal tubular reabsorption of phosphate. Cellular phosphate uptake is stimulated by various factors and conditions, including alkalonia, insulin, epinephrine, feeding, hungry bone syndrome, and accelerated cell proliferation.

Phosphorus metabolism and homeostasis are intimately related to calcium metabolism. See sections on metabolic bone disease in Chapter 26.

**HYPOPHOSPHATEMIA**

### General Considerations

The leading causes of hypophosphatemia are listed in Table 21–9. Hypophosphatemia may occur in the presence of normal phosphate stores. Serious depletion of body phosphate stores may exist with low, normal, or high serum phosphate concentrations.

Serum phosphate levels decrease transiently after food intake, thus fasting samples are recommended for accuracy. **Moderate hypophosphatemia** (1.0–2.4 mg/dL [or 0.32–0.79 mmol/L]) occurs commonly in hospitalized patients and may not reflect decreased phosphate stores.

In **severe hypophosphatemia** (< 1 mg/dL [or < 0.32 mmol/L]), the affinity of hemoglobin for oxygen increases through a decrease in the erythrocyte 2,3-diphosphoglycerate concentration, impairing tissue oxygenation and cell metabolism and resulting in muscle weakness or even rhabdomyolysis. Severe hypophosphatemia is common and multifactorial in alcoholic patients. In acute alcohol withdrawal, increased plasma insulin and epinephrine along with respiratory alkalosis promote intracellular shift of phosphate. Vomiting, diarrhea, and poor dietary intake contribute to hypophosphatemia. Chronic alcohol use results in a decrease in the renal threshold of phosphate excretion. This renal tubular dysfunction reverses after a month of abstinence. Patients with chronic obstructive pulmonary disease and asthma commonly have hypophosphatemia, attributed to xanthine derivatives causing shifts of phosphate intracellularly and the phosphaturic effects of β-adrenergic agonists, loop diuretics, xanthine derivatives, and corticosteroids. The metabolic syndrome, a major contributor to coronary heart disease risk, is associated with low phosphate (and magnesium) levels but the clinical significance of these disturbances is unclear. Refeeding or glucose administration to phosphate-depleted patients may cause fatal hypophosphatemia.

### Clinical Findings

#### A. Symptoms and Signs

Acute, severe hypophosphatemia (< 1.0 mg/dL [or < 0.32 mmol/L]) can lead to rhabdomyolysis, paresthesias, and encephalopathy (irritability, confusion, dysarthria, seizures, and coma). Respiratory failure or failure to wean from mechanical ventilation may occur as a result of diaphragmatic weakness. Arrhythmias and heart failure are uncommon but serious manifestations. Hematologic manifestations include acute hemolytic anemia from erythrocyte fragility, platelet dysfunction with petechial hemorrhages, and impaired chemotaxis of leukocytes (leading to increased susceptibility to gram-negative sepsis). Chronic severe depletion may cause anorexia, pain in muscles and bones, and fractures.

FGF23, fibroblast growth factor 23.
When to Admit

Patients with severe or refractory hypophosphatemia will require intravenous phosphate.

HYPERPHOSPHATEMIA

Advanced CKD is the most common cause. Hyperphosphatemia in the presence of hypercalcemia imposes a high risk of metastatic calcification.

General Considerations

Advanced CKD with decreased urinary excretion of phosphate is the most common cause of hyperphosphatemia. Other causes are listed in Table 21–10.

Clinical Findings
A. Symptoms and Signs

The clinical manifestations are those of the underlying disorder or associated condition.

B. Laboratory Findings

In addition to elevated phosphate, blood chemistry abnormalities are those of the underlying disease.

Treatment

Treatment is directed at the underlying cause. Exogenous sources of phosphate, including enteral or parenteral nutrition and medications, should be reduced or eliminated. Dietary phosphate absorption can be reduced by oral phosphate binders, such as calcium carbonate, calcium acetate, sevelamer carbonate, lanthanum carbonate, and aluminum hydroxide. Sevelamer, lanthanum, and aluminum may be used in patients with hypercalcemia, although aluminum use should be limited to a few days because of the risk of aluminum accumulation and neurotoxicity. In acute kidney injury and advanced CKD, dialysis will reduce serum phosphate.

When to Admit

Patients with acute severe hyperphosphatemia require hospitalization for emergent therapy, possibly including dialysis. Concomitant illnesses, such as acute kidney injury or cell lysis, may necessitate admission.

Hypomagnesemia

Essentials of Diagnosis

- Serum concentration of magnesium may not be decreased even in the presence of magnesium depletion. Check urinary magnesium excretion if renal magnesium wasting is suspected.
- Causes neurologic symptoms and arrhythmias.
- Impairs release of PTH.

General Considerations

Causes of hypomagnesemia are listed in Table 21–11. Normomagnesemia does not exclude magnesium depletion because only 1% of total body magnesium is in the extracellular fluid (ECF). Hypomagnesemia and hypokalemia share many etiologies, including diuretics, diarrhea, alcoholism, aminoglycosides, and amphotericin. Renal potassium wasting also occurs from hypomagnesemia, and is refractory to potassium replacement until magnesium is repleted. Hypomagnesemia also suppresses PTH release and causes end-organ resistance to PTH and low 1,25-dihydroxyvitamin D₃ levels. The resultant hypocalcemia is refractory to calcium replacement until the magnesium is normalized. Molecular mechanisms of magnesium wasting have been revealed in some hereditary disorders. The FDA has issued a warning about hypomagnesemia for patients taking proton pump inhibitors. The presumed mechanism is decreased

DISORDERS OF MAGNESIUM CONCENTRATION

Normal plasma magnesium concentration is 1.8–3.0 mg/dL (or 0.75–1.25 mmol/L), with about one-third bound to protein and two-thirds existing as free cation. Magnesium excretion is via the kidney. Magnesium’s physiologic effects on the nervous system resemble those of calcium.

Altered magnesium concentration usually provokes an associated alteration of Ca²⁺. Both hypomagnesemia and hypermagnesemia can decrease PTH secretion or action. Severe hypermagnesemia (> 5 mg/dL [or 2.1 mmol/L]) suppresses PTH secretion with consequent hypocalcemia; this disorder is typically seen only in patients receiving magnesium therapy for preeclampsia. Severe hypomagnesemia causes PTH resistance in end-organs and eventually decreased PTH secretion in severe cases.

intestinal magnesium absorption, but it is not clear why this complication develops in only a small fraction of patients taking these medications.

► Clinical Findings
A. Symptoms and Signs

Common symptoms are those of hypokalemia and hypocalcemia, with weakness and muscle cramps. Marked neuromuscular and central nervous system hyperirritability may produce tremors, athetoid movements, jerking, nystagmus, a Babinski response, confusion, and disorientation. Cardiovascular manifestations include hypertension, tachycardia, and ventricular arrhythmias.

B. Laboratory Findings

Urinary excretion of magnesium exceeding 10–30 mg/day or a fractional excretion > 2% indicates renal magnesium wasting. Hypokalemia and hypocalcemia are often present. The ECG shows a prolonged QT interval, due to lengthening of the ST segment. PTH secretion is often suppressed (see Hypocalcemia, above).

► Treatment

Magnesium oxide, 250–500 mg orally once or twice daily, is useful for treating chronic hypomagnesemia. Symptomatic hypomagnesemia requires intravenous magnesium sulfate 1–2 g over 5–60 minutes mixed in either dextrose 5% or 0.9% normal saline. Torsades de pointes in the setting of hypomagnesemia can be treated with 1–2 g of magnesium sulfate in 10 mL of dextrose 5% solution pushed intravenously over 15 minutes. Severe, non–life-threatening deficiency can be treated at a rate to 1–2 g/h over 3–6 hours. Magnesium sulfate may also be given intramuscularly in a dosage of 200–800 mg/day (8–33 mmol/day) in four divided doses. Serum levels must be monitored daily and dosage adjusted to keep the concentration from rising above 3 mg/dL. Tendon reflexes may be checked for hyporeflexia of hypomagnesemia. K+ and Ca2+ replacement may be required, but patients with hypokalemia and hypocalcemia of hypomagnesemia do not recover without magnesium supplementation.

Patients with normal kidney function can excrete excess magnesium; hypomagnesemia should not develop with replacement dosages. In patients with CKD, magnesium replacement should be done cautiously to avoid hypermagnesemia. Reduced doses (50–75% dose reduction) and more frequent monitoring (at least twice daily) are indicated.

CMDT 2013

889

PCO₂. The \( \text{HCO}_3^- \) value is calculated from the Henderson–Hasselbalch equation:

\[
\text{pH} = 6.1 + \log \left( \frac{\text{HCO}_3^-}{0.03 \times \text{PCO}_2} \right)
\]

The total venous CO₂ measurement is a more direct determination of \( \text{HCO}_3^- \). Because of the dissociation characteristics of carbonic acid (\( \text{H}_2\text{CO}_3 \)) at body pH, dissolved CO₂ is almost exclusively in the form of \( \text{HCO}_3^- \), and for clinical purposes the total carbon dioxide content is equivalent (± 3 mEq/L) to the \( \text{HCO}_3^- \) concentration:

\[
\text{H}^+ + \text{HCO}_3^- \leftrightarrow \text{H}_2\text{CO}_3 \leftrightarrow \text{CO}_2 + \text{H}_2\text{O}
\]

Venous blood gases can provide useful information for acid–base assessment since the arteriovenous differences in pH and PCO₂ are small and relatively constant. Venous blood pH is usually 0.03–0.04 units lower than arterial blood pH, and venous blood PCO₂ is 7 or 8 mm Hg higher than arterial blood PCO₂. Calculated \( \text{HCO}_3^- \) concentration in venous blood is at most 2 mEq/L higher than arterial blood \( \text{HCO}_3^- \). Arterial and venous blood gases will not be equivalent during a cardiopulmonary arrest; arterial samples should be obtained for the most accurate measurements of pH and PCO₂.

**TYPES OF ACID–BASE DISORDERS**

There are two types of acid–base disorders: acidosis and alkalosis. These disorders can be either metabolic (decreased or increased \( \text{HCO}_3^- \)) or respiratory (decreased or increased PCO₂). Primary respiratory disorders affect blood acidity by changes in PCO₂ and primary metabolic disorders are disturbances in \( \text{HCO}_3^- \) concentration. A primary disturbance is usually accompanied by a compensatory response, but the compensation does not fully correct the pH disturbance of the primary disorder. If the pH is < 7.40, the primary process is acidosis, either respiratory (PCO₂ > 40 mm Hg) or metabolic (\( \text{HCO}_3^- < 24 \text{ mEq/L} \)). If the pH is higher than 7.40, the primary process is alkalosis, either respiratory (PCO₂ < 40 mm Hg) or metabolic (\( \text{HCO}_3^- > 24 \text{ mEq/L} \)). One respiratory or metabolic disorder with its appropriate compensatory response is a simple acid-base disorder.

**MIXED ACID–BASE DISORDERS**

Two or three simultaneous disorders can be present in a mixed acid-base disorder, but there can never be two primary respiratory disorders. Uncovering a mixed acid-base disorder is clinically important, but requires a methodical approach to acid-base analysis (see box, Step-by-Step Analysis of Acid-Base Status). Once the primary disturbance has been determined, the clinician should assess whether the compensatory response is appropriate (Table 21–12). An inadequate or an exaggerated response indicates the presence of another primary acid-base disturbance.

The anion gap should always be calculated for two reasons. First, it is possible to have an abnormal anion

---

**STEP-BY-STEP ANALYSIS OF ACID-BASE STATUS**

**Step 1:** Determine the primary (or main) disorder—whether it is metabolic or respiratory—from blood pH, \( \text{HCO}_3^- \), and PCO₂ values.

**Step 2:** Determine the presence of mixed acid-base disorders by calculating the range of compensatory responses (Table 21–12).

**Step 3:** Calculate the anion gap (Table 21–13).

**Step 4:** Calculate the corrected \( \text{HCO}_3^- \) concentration if the anion gap is increased (see above).

**Step 5:** Examine the patient to determine whether the clinical signs are compatible with the acid-base analysis.

---

**Table 21–12.** Primary acid-base disorders and expected compensation.

gap even if the sodium, chloride, and bicarbonate levels are normal. Second, a large anion gap (> 20 mEq/L) suggests a primary metabolic acid-base disturbance regardless of the pH or serum bicarbonate level because a markedly abnormal anion gap is never a compensatory response to a respiratory disorder. In patients with an increased anion gap metabolic acidosis, clinicians should calculate the corrected bicarbonate. In increased anion gap acidoses, there should be a mole for mole decrease in \( \text{HCO}_3^- \) as the anion gap increases. A corrected \( \text{HCO}_3^- \) value higher or lower than normal (24 mEq/L) indicates the concomitant presence of metabolic alkalosis or normal anion gap metabolic acidosis, respectively.

Indicates a primary metabolic acid-base disturbance regardless of the pH or serum bicarbonate level. A decreased anion gap can occur because of a reduction in unmeasured anions or an increase in unmeasured cations. In hypochloremia, a 2 mEq/L decrease in anion gap will occur for every 1 g/dL decline in serum albumin.

**INCREASED ANION GAP ACIDOSIS (Increased Unmeasured Anions)**

Normochloremic metabolic acidosis generally results from addition of organic acids such as lactate, acetacetate, \( \beta \)-hydroxybutyrate, and exogenous toxins. Other anions such as isocitrate, \( \alpha \)-ketoglutarate, malate and \( \beta \)-lactate, may contribute to the anion gap of lactic acidosis, DKA, and acidosis of unknown etiology. Uremia causes an increased anion gap metabolic acidosis from unexcreted organic acids and anions.

**A. Lactic Acidosis**

Lactic acid is formed from pyruvate in anaerobic glycolysis, typically in tissues with high rates of glycolysis, such as gut (responsible for over 50% of lactate production), skeletal muscle, brain, skin, and erythrocytes. Normally, lactate levels
remain low (1 mEq/L) because of metabolism of lactate principally by the liver through gluconeogenesis or oxidation via the Krebs cycle. The kidneys metabolize about 30% of lactate.

In lactic acidosis, lactate levels are at least 4–5 mEq/L but commonly 10–30 mEq/L. There are two basic types of lactic acidosis.

**Type A (hypoxic) lactic acidosis** is more common, resulting from decreased tissue perfusion; cardiogenic, septic, or hemorrhagic shock; and carbon monoxide or cyanide poisoning. These conditions increase peripheral lactic acid production and decrease hepatic metabolism of lactate as liver perfusion declines.

**Type B lactic acidosis** may be due to metabolic causes (eg, diabetes, ketoacidosis, liver disease, kidney disease, infection, leukemia, or lymphoma) or toxins (eg, ethanol, methanol, salicylates, isoniazid, or metformin). Propylene glycol can cause lactic acidosis from decreased liver metabolism; it is used as a vehicle for intravenous drugs, such as nitroglycerin, etomidate, and diazepam. Parenteral nutrition without thiamine causes severe refractory lactic acidosis from decreased liver perfusion.

Type B lactic acidosis is more common, resulting from decreased tissue perfusion; cardiogenic, septic, or hemorrhagic shock; and carbon monoxide or cyanide poisoning. These conditions increase peripheral lactic acid production and decrease hepatic metabolism of lactate as liver perfusion declines.

**C. Alcoholic Ketoadicosis**

Chronically malnourished patients who consume large quantities of alcohol daily may develop alcoholic ketoacidosis. Most of these patients have mixed acid–base disorders (10% have a triple acid–base disorder). Although decreased HCO₃⁻ is usual, 50% of the patients may have normal or alkalemic pH. Three types of metabolic acidosis are seen in alcoholic ketoacidosis: (1) Ketoadicosis is due to β-hydroxybutyrate and acetacetate excess. (2) Lactic acidosis: Alcohol metabolism increases the NADH:NAD ratio, causing increased production and decreased utilization of lactate. Accompanying thiamine deficiency, which inhibits pyruvate carboxylase, further enhances lactic acid production in many cases. Moderate to severe elevations of lactate (> 250 mg/dL) are seen with concomitant disorders such as sepsis, pancreatitis, or hypoglycemia. (3) Hyperchloremic acidosis from bicarbonate loss in the urine is associated with ketonuria (see above). Metabolic alkalosis occurs from volume contraction and vomiting. Respiratory alkalosis results from alcohol withdrawal, pain, or associated disorders such as sepsis or liver disease. Half of the patients have hypoglycemia or hyperglycemia. When serum glucose levels are > 250 mg/dL, the distinction from DKA is difficult. The absence of a diabetic history and normoglycemia after initial therapy support the diagnosis of alcoholic ketoacidosis.

**D. Toxins**

(See also Chapter 38.) Multiple toxins and drugs increase the anion gap by increasing endogenous acid production. Common examples include methanol (metabolized to formaldehyde), ethylene glycol (glycolic and oxalic acid), and salicylates (salicylic acid and lactic acid). The latter can cause a mixed disorder of metabolic acidosis with respiratory alkalosis. In toluene poisoning, a metabolite hippurate is rapidly excreted by the kidney and may present as a normal anion gap acidosis. Isopropanol, which is metabolized to acetone, increases the osmolar gap, but not the anion gap.

**E. Uremic Acidosis**

As the GFR drops below 15–30 mL/min, the kidneys are increasingly unable to excrete H⁺ and organic acids, such as phosphate and sulfate, resulting in an increased anion gap acidosis. Hyperchloremic normal anion gap acidosis develops in earlier stages of CKD.

**NORMAL ANION GAP ACIDOSIS**

(Table 21–14)

The two major causes are gastrointestinal HCO₃⁻ loss and defects in renal acidification (renal tubular acidoses). The urinary anion gap can differentiate between these causes (see below).
A. Gastrointestinal HCO₃⁻ Loss

The gastrointestinal tract secretes bicarbonate at multiple sites. Small bowel and pancreatic secretions contain large amounts of HCO₃⁻; massive diarrhea or pancreatic drainage can result in HCO₃⁻ loss. Hyperchloremia occurs because the ileum and colon secrete HCO₃⁻ in exchange for Cl⁻ by countertransport. The resultant volume contraction causes increased Cl⁻ retention by the kidney in the setting of decreased HCO₃⁻. Patients with ureterosigmoidostomies can develop hyperchloremic metabolic acidosis because the colon secretes HCO₃⁻ in the urine in exchange for Cl⁻.

B. Renal Tubular Acidosis (RTA)

Hyperchloremic acidosis with a normal anion gap and normal (or near normal) GFR, and in the absence of diabetes, defines RTA. The defect is either inability to excrete H⁺ (inadequate generation of new HCO₃⁻) or inappropriate reabsorption of HCO₃⁻. Three major types can be differentiated by the clinical setting, urinary pH, urinary anion gap (see below), and serum K⁺ level. The pathophysiologic mechanisms of RTA have been elucidated by identifying the responsible molecules and gene mutations.

1. Classic distal RTA (type I)—This disorder is characterized by selective deficiency in H⁺ secretion in α intercalated cells in the collecting tubule. Despite acidosis, urinary pH cannot be acidified and is above 5.5, which retards the binding of H⁺ to phosphate (H⁺ + HPO₄²⁻ → H₂PO₄⁻) and inhibits titratable acid excretion. Furthermore, urinary excretion of NH₄⁺ and K⁺ is decreased, and the urinary anion gap is positive (see below). Enhanced K⁺ excretion occurs probably because there is less competition from H⁺ in the distal nephron transport system. Furthermore, hyperaldosteronism occurs in response to renal salt wasting, which will increase potassium excretion. Nephrocalcinosis and nephrolithiasis are often seen in patients with distal RTA since chronic acidosis decreases tubular calcium reabsorption. Hypercalciuria, alkaline urine, and lowered level of urinary citrate cause calcium phosphate stones and nephrocalcinosis.

Distal RTA develops as a consequence of paraproteinemias, autoimmune disease, and drugs and toxins such as amphotericin.

2. Proximal RTA (type II)—Proximal RTA is due to a selective defect in the proximal tubule’s ability to reabsorb filtered HCO₃⁻. Carbonic anhydrase inhibitors (acetazolamide) can cause proximal RTA. About 90% of filtered HCO₃⁻ is absorbed by the proximal tubule. A proximal defect in HCO₃⁻ reabsorption will overwhelm the distal tubule’s limited capacity to reabsorb HCO₃⁻, resulting in bicarbonaturia and metabolic acidosis. Distal delivery of HCO₃⁻ declines as the plasma HCO₃⁻ level decreases. When the plasma HCO₃⁻ level drops to 15–18 mEq/L, the distal nephron can reabsorb the diminished filtered load of HCO₃⁻. Bicarbonaturia resolves, and the urinary pH can be acidic. Thiazide-induced volume contraction can be used to enhance proximal HCO₃⁻ reabsorption, leading to the decrease in distal HCO₃⁻ delivery and improvement of bicarbonaturia and renal acidification. The increased delivery of HCO₃⁻ to the distal nephron increases K⁺ secretion, and hypokalemia results if a patient is loaded with excess HCO₃⁻ and K⁺ is not adequately supplemented. Proximal RTA can exist with other proximal reabsorption defects, such as Fanconi syndrome, resulting in glucosuria, aminoaciduria, phosphaturia, and uricosuria. Causes include multiple myeloma and nephrotoxic drugs.

3. Hyporeninemic hypoaldosteronemic RTA (type IV)—Type IV is the most common RTA in clinical practice. The defect is aldosterone deficiency or antagonism, which impairs distal nephron Na⁺ reabsorption and K⁺ and H⁺ excretion. Renal salt wasting and hyperkalemia are frequently present. Common causes are diabetic nephropathy, tubulointerstitial renal diseases, hypertensive nephrosclerosis, and AIDS. In patients with these disorders, drugs, such as ACE inhibitors, spironolactone, and NSAIDs, can exacerbate the hyperkalemia.
C. Dilutional Acidosis

Rapid dilution of plasma volume by 0.9% NaCl may cause hyperchloremic acidosis.

D. Recovery from DKA

See earlier section, Increased Anion Gap Acidosis (Increased Unmeasured Anion).

E. Posthypocapnia

In prolonged respiratory alkalosis, HCO$_3^-$ decreases and Cl$^-$ increases from decreased renal NH$_4^+$Cl excretion. If the respiratory alkalosis is corrected quickly, HCO$_3^-$ will remain low until the kidneys can generate new HCO$_3^-$, which generally takes several days. In the meantime, the increased Pco$_2$ with low HCO$_3^-$ causes metabolic acidosis.

F. Hyperalimentation

Hyperalimentation fluids may contain amino acid solutions that acidify when metabolized, such as arginine hydrochloride and lysine hydrochloride.

Assessment of Hyperchloremic Metabolic Acidosis by Urinary Anion Gap

Increased renal NH$_4^+$Cl excretion to enhance H$^+$ removal is the normal physiologic response to metabolic acidosis. The daily urinary excretion of NH$_4$Cl can be increased from 30 mEq to 200 mEq in response to acidosis.

The urinary anion gap (Na$^+$ + K$^+$ – Cl$^-$) reflects the ability of the kidney to excrete NH$_4$Cl. The urinary anion gap differentiates between gastrointestinal and renal causes of hyperchloremic acidosis. If the cause is gastrointestinal HCO$_3^-$ loss (diarrhea), renal acidification remains normal and NH$_4$Cl excretion increases, and the urinary anion gap is negative. If the cause is distal RTA, the urinary anion gap is positive, since the basic lesion in the disorder is the inability of the kidney to excrete H$^+$ as NH$_4$Cl. In proximal (type I) RTA, the kidney has defective HCO$_3^-$ reabsorption, leading to increased HCO$_3^-$ excretion rather than decreased NH$_4$Cl excretion; the urinary anion gap is often negative.

Urinary pH may not readily differentiate between the two causes. Despite acidosis, if volume depletion from diarrhea causes inadequate Na$^+$ delivery to the distal nephron and therefore decreased exchange with H$^+$, urinary pH may not be lower than 5.3. In the presence of this relatively high urinary pH, however, H$^+$ excretion continues due to buffering of NH$_3$ to NH$_4^+$, since the Pk of this reaction is as high as 9.1. Potassium depletion, which can accompany diarrhea (and surreptitious laxative abuse), may also impair renal acidification. Thus, when volume depletion is present, the urinary anion gap is a better measure of ability to acidify the urine than urinary pH.

When large amounts of other anions are present in the urine, the urinary anion gap may not be reliable. In such a situation, NH$_4^+$ excretion can be estimated using the urinary osmolar gap:

\[
\text{NH}_4^+ \text{ excretion (mmol/L)} = 0.5 \times \text{Urinary osmolar gap} = 0.5 \times [U \text{ osm} - 2(U \text{ Na}^+ + U \text{ K}^+) + U \text{ urea} + U \text{ glucose}]
\]

where urine concentrations and osmolality are in mmol/L.

Clinical Findings

A. Symptoms and Signs

Symptoms of metabolic acidosis are mainly those of the underlying disorder. Compensatory hyperventilation is an important clinical sign and may be misinterpreted as a primary respiratory disorder; Kussmaul breathing (deep, regular, sighing respirations) may be seen with severe metabolic acidosis.

B. Laboratory Findings

Blood pH, serum HCO$_3^-$, and Pco$_2$ are decreased. Anion gap may be normal (hyperchloremic) or increased (normochloremic). Hyperkalemia may be seen (see above).

Treatment

A. Increased Anion Gap Acidosis

Treatment is aimed at the underlying disorder, such as insulin and fluid therapy for diabetes and appropriate volume resuscitation to restore tissue perfusion. The metabolism of lactate will produce HCO$_3^-$ and increase pH. Supplemental HCO$_3^-$ is indicated for treatment of hyperkalemia (Table 21–6) and some forms of normal anion gap acidosis but has been controversial for treatment of increased anion gap metabolic acidosis with respect to efficacy and safety. Large amounts of HCO$_3^-$ may have deleterious effects, including hypernatremia, hyperosmolality, volume overload, and worsening of intracellular acidosis.

In addition, alkali administration stimulates phosphofructokinase activity, thus exacerbating lactic acidosis via enhanced lactate production. Ketogenesis is also augmented by alkali therapy.

In salicylate intoxication, alkali therapy must be started unless blood pH is already alkalinized by respiratory alkalosis, since an increased pH converts salicylate to more impermeable salicylic acid, decreasing central nervous system damage. In alcoholic ketoacidosis, thiamine should be given with glucose to avoid Wernicke encephalopathy. The bicarbonate deficit can be calculated as follows:

\[
\text{HCO}_3^- \text{ deficit} = 0.5 \times \text{body weight in kg} \times (24 - \text{HCO}_3^-)
\]

Half of the calculated deficit should be administered within the first 3–4 hours to avoid overcorrection and volume overload. In methanol intoxication, ethanol had been used as a competitive substrate for alcohol dehydrogenase, which metabolizes methanol to formaldehyde. Inhibition of alcohol dehydrogenase by fomepizole is the standard of care.

B. Normal Anion Gap Acidosis

Treatment of RTA is mainly achieved by administration of alkali (either as bicarbonate or citrate) to correct metabolic abnormalities and prevent nephrocalcinosis and CKD.
Large amounts of oral alkali (10–15 mEq/kg/d) (Table 21–14) may be required to treat proximal RTA because most of the alkali is excreted into the urine, which exacerbates hypokalemia. Thus, a mixture of sodium and potassium salts is preferred. Thiazides may reduce the amount of alkali required, but hypokalemia may develop. Treatment of type 1 distal RTA requires less alkali (1–3 mEq/kg/d) than proximal RTA. Potassium supplementation may be necessary.

For type IV RTA, dietary potassium restriction may be necessary and potassium-retaining drugs should be withdrawn. Fludrocortisone may be effective in cases with hypokaldosteronism, but should be used with care, preferably in combination with loop diuretics. In some cases, oral alkali supplementation (1–3 mEq/kg/d) may be required.

**When to Refer**

Most clinicians will refer patients with renal tubular acidoses to a nephrologist for evaluation and possible alkali therapy.

**When to Admit**

Patients will require emergency department evaluation or hospital admission depending on the severity of the acidoses and underlying conditions.

</tbody>
</table>

Hypotension and orthostasis may be seen. In vomiting or nasogastric suction, loss of acid (HCl) initiates the alkalosis, but volume contraction from Cl\(^-\) loss maintains the alkalosis because the kidney avidly reabsorbs Na\(^+\) to restore the ECF. Increased sodium reabsorption necessitates increased HCO\(_3\)\(^-\) reabsorption proximally, and the urinary pH remains acidic despite alkalemia (paradoxical aciduria). Renal Cl\(^-\) reabsorption is high, and urine Cl\(^-\) is low (<10–20 mEq/L). In alkalosis, bicarbonaturia may force Na\(^+\) excretion as the accompanying cation even if volume depletion is present. Therefore, urine Cl\(^-\) is preferred to urine Na\(^+\) as a measure of extracellular volume. Diuretics may limit the utility of urine chloride by increasing urine chloride and sodium excretion, even in the setting of volume contraction.

Metabolic alkalosis is generally associated with hypokalemia due to the direct effect of alkalosis on renal potassium excretion and secondary hyperaldosteronism from volume depletion. Hypokalemia exacerbates the metabolic alkalosis by increasing bicarbonate reabsorption in the proximal tubule and hydrogen ion secretion in the distal tubule. Administration of KCl will correct the disorder.

1. **Contraction alkalosis**—Diuretics decrease extracellular volume from urinary loss of NaCl and water. The plasma HCO\(_3\)\(^-\) concentration increases because the extracellular fluid volume contracts around a stable total body bicarbonate. Contraction alkalosis is the opposite of dilutional acidosis.

2. **Posthypercapnia alkalosis**—In chronic respiratory acidosis, the kidney decreases bicarbonate excretion, increasing plasma HCO\(_3\)\(^-\) concentration (Table 21–12). Hypercapnia directly affects the proximal tubule to decrease NaCl reabsorption, which can cause extracellular volume depletion. If P\(_{\text{CO}_2}\) is rapidly corrected, metabolic alkalosis will exist until the kidney excretes the retained bicarbonate. Many patients with chronic respiratory acidosis receive diuretics, which further exacerbates the metabolic alkalosis.

**B. Saline-Unresponsive Alkalosis**

1. **Hyperaldosteronism**—Primary hyperaldosteronism causes extracellular volume expansion and hypertension by increasing distal sodium reabsorption. Aldosterone increases H\(^+\) and K\(^+\) excretion, producing metabolic alkalosis and hypokalemia. In an attempt to decrease extracellular volume, high levels of NaCl are excreted with a high urine Cl\(^-\) (>20 mEq/L). Therapy with NaCl will increase volume expansion and hypertension and will not treat the underlying problem of mineralocorticoid excess.

2. **Alkali administration with decreased GFR**—The normal kidney has a substantial capacity for bicarbonate excretion, protecting against metabolic alkalosis even with large HCO\(_3\)\(^-\) intake. However, urinary excretion of bicarbonate is inadequate in CKD. If large amounts of HCO\(_3\)\(^-\) are consumed, as with intensive antacid therapy, metabolic alkalosis will occur. Lactate, citrate, and gluconate can also cause metabolic alkalosis because they are metabolized to bicarbonate. In milk-alkali syndrome, sustained heavy ingestion of absorbable antacids and milk causes hypercalcemic kidney injury and metabolic alkalosis. Volume contraction from renal hypercalcemic effects exacerbates the alkalosis.

**Clinical Findings**

**A. Symptoms and Signs**

There are no characteristic symptoms or signs. Orthostatic hypotension may be encountered. Concomitant hypokalemia may cause weakness and hyporeflexia. Tetany and neuromuscular irritability occur rarely.

**B. Laboratory Findings**

The arterial blood pH and bicarbonate are elevated. With respiratory compensation, the arterial P\(_{\text{CO}_2}\) is increased. Serum potassium and chloride are decreased. There may be an increased anion gap. The urine chloride can differentiate between saline-responsive (<25 mEq/L) and unresponsive (>40 mEq/L) causes.

**Treatment**

Mild alkalosis is generally well tolerated. Severe or symptomatic alkalosis (pH >7.60) requires urgent treatment.

**A. Saline-Responsive Metabolic Alkalosis**

Therapy for saline-responsive metabolic alkalosis is correction of the extracellular volume deficit with isotonic saline. Diuretics should be discontinued. H\(_+\)-blockers or proton pump inhibitors may be helpful in patients with alkalosis from nasogastric suctioning. If pulmonary or cardiovascular disease prohibits adequate resuscitation, acetazolamide will increase renal bicarbonate excretion. Hypokalemia may develop because bicarbonate excretion may induce kaliuresis. Severe cases, especially those with reduced kidney function, may require dialysis with low-bicarbonate dialysate.

**B. Saline-Unresponsive Metabolic Alkalosis**

Therapy for saline-unresponsive metabolic alkalosis includes surgical removal of a mineralocorticoid-producing tumor and blockage of aldosterone effect with an ACE inhibitor or with spironolactone. Metabolic alkalosis in primary aldosteronism can be treated only with potassium repletion.

**RESPIRATORY ACIDOSIS (HYPERCAPNIA)**

Respiratory acidosis results from hypoventilation and subsequent hypercapnia. Pulmonary and extrapulmonary disorders can cause hypoventilation.
Acute respiratory failure is associated with severe acidosis and only a small increase in the plasma bicarbonate. After 6–12 hours, the primary increase in PCO₂ evokes a renal compensation to excrete more acid and to generate more HCO₃⁻; complete metabolic compensation by the kidney takes several days.

Chronic respiratory acidosis is generally seen in patients with underlying lung disease, such as chronic obstructive pulmonary disease. Renal excretion of acid as NH₄Cl results in hypochloremia. When chronic respiratory acidosis is corrected suddenly, posthypercapnic metabolic alkalosis ensues until the kidneys excrete the excess bicarbonate over 2–3 days.

**Clinical Findings**

**A. Symptoms and Signs**

With acute onset, somnolence, confusion, mental status changes, asterixis, and myoclonus may develop. Severe hypercapnia increases cerebral blood flow, cerebrospinal fluid pressure, and intracranial pressure; papilledema and pseudotumor cerebri may be seen.

**B. Laboratory Findings**

Arterial pH is low and PCO₂ is increased. Serum HCO₃⁻ is elevated but does not fully correct the pH. If the disorder is chronic, hypochloremia is seen.

**Treatment**

If opioid overdose is a possible diagnosis or there is no other obvious cause for hypoventilation, the clinician should consider a diagnostic and therapeutic trial of intravenous naloxone (see Chapter 38). In all forms of respiratory acidosis, treatment is directed at the underlying disorder to improve ventilation.

As in respiratory acidosis, the metabolic compensation is greater if the respiratory alkalosis is chronic (Table 21–12). Although serum HCO₃⁻ is frequently < 15 mEq/L in metabolic acidosis, such a low level in respiratory alkalosis is unusual and may represent a concomitant primary metabolic acidosis.

**Clinical Findings**

**A. Symptoms and Signs**

In acute cases (hyperventilation), there is light-headedness, anxiety, perioral numbness, and paresthesias. Tetany occurs from a low ionized calcium, since severe alkalosis increases calcium binding to albumin.

**B. Laboratory Findings**

Arterial blood pH is elevated, and PCO₂ is low. Serum bicarbonate is decreased in chronic respiratory alkalosis.

**Treatment**

Treatment is directed toward the underlying cause. In acute hyperventilation syndrome from anxiety, the traditional treatment of breathing into a paper bag should be discouraged because it does not correct PCO₂ and may decrease Po₂. Reassurance may be sufficient for the

**RESPIRATORY ALKALOSIS (HYPOCAPNIA)**

Respiratory alkalosis occurs when hyperventilation reduces the PCO₂, increasing serum pH. The most common cause of respiratory alkalosis is hyperventilation syndrome (Table 21–16), but bacterial septicemia and cirrhosis are other common causes. In pregnancy, progesterone stimulates the respiratory center, producing an average PCO₂ of 30 mm Hg and respiratory alkalosis. Symptoms of acute respiratory alkalosis are related to decreased cerebral blood flow induced by the disorder.

Determination of appropriate metabolic compensation may reveal an associated metabolic disorder (see above under Mixed Acid–Base Disorders).
anxious patient, but sedation may be necessary if the process persists. Hyperventilation is usually self-limited since muscle weakness caused by the respiratory alkalemia will suppress ventilation. Rapid correction of chronic respiratory alkalosis may result in metabolic acidosis as $P_{\text{CO}_2}$ is increased in the setting of a previous compensatory decrease in $HCO_3^-$. 

**FLUID MANAGEMENT**

Daily parenteral maintenance fluids and electrolytes for an average adult would include 2500–3000 mL of 5% dextrose in 0.2% saline solution (34 mEq Na\(^+\) plus 34 mEq Cl\(^-\)) with 30 mEq/L of KCl. Guidelines for gastrointestinal fluid losses are shown in Table 21–17.

Weight loss or gain is the best indication of water balance. Insensible water loss should be considered in febrile patients. Water loss increases by 100–150 mL/d for each degree of body temperature over 37°C.

In patients requiring maintenance and possibly replacement of fluid and electrolytes by parenteral infusion, the total daily ration should be administered continuously over 24 hours to ensure optimal utilization.

If intravenous fluids are the only source of water, electrolytes, and calories for longer than a week, parenteral nutrition containing amino acids, lipids, trace metals, and vitamins may be indicated. (See Chapter 29.)

For parenteral alimentation, 620 mg (20 mmol) of phosphorus is required for every 1000 nonprotein kcal to maintain phosphate balance and to ensure anabolic function. For prolonged parenteral fluid maintenance, a daily ration is 620–1240 mg (20–40 mmol) of phosphorus.

\(^1\)In the absence of diarrhea, colonic fluid Na\(^+\) levels are low (40 mEq/L).
Kidney disease can be discovered incidentally during a routine medical evaluation or with evidence of kidney dysfunction, such as hypertension, edema, nausea, or hematuria. The initial approach in both situations should be to assess the cause and severity of renal abnormalities. In all cases this evaluation includes (1) an estimation of disease duration, (2) a careful urinalysis, and (3) an assessment of the glomerular filtration rate (GFR). The history and physical examinations, though equally important, are variable among renal syndromes—thus, specific symptoms and signs are discussed under each disease entity.

### Assessment of Kidney Disease

#### Disease Duration

Kidney disease may be acute or chronic. Acute kidney injury, also known as acute renal failure, is worsening of kidney function over hours to days, resulting in the retention of nitrogenous wastes (such as urea nitrogen) and creatinine in the blood. Retention of these substances is called azotemia. Chronic kidney disease (CKD) results from an abnormal loss of kidney function over months to years. Differentiating between the two is important for diagnosis, treatment, and outcome. Oliguria is unusual in CKD. Anemia (from low kidney erythropoietin production) is rare in the initial period of acute kidney disease. Small kidneys are most consistent with CKD, whereas normal to large-size kidneys can be seen with both chronic and acute disease.

#### Urinalysis

A urinalysis can provide information similar to a renal biopsy in a way that is cost-effective and, of course, noninvasive. The urine is collected in midstream or, if that is not feasible, by bladder catheterization. The urine should be examined within 1 hour after collection to avoid destruction of formed elements. Urinalysis includes a dipstick examination followed by microscopic assessment if the dipstick has positive findings. The dipstick examination measures urinary pH, protein, hemoglobin, glucose, ketones, bilirubin, nitrites, and leukocyte esterase. Urinary specific gravity is often reported, too. Microscopy searches for all formed elements—crystals, cells, casts, and infecting organisms.

Various findings on the urinalysis are indicative of certain patterns of kidney disease. A bland (normal) urinary sediment is common, especially in CKD and acute disorders that are not intrinsic to the kidney, such as limited effective blood flow to the kidney or obstruction of outflow of urine. Casts are composed of Tamm-Horsfall urinary mucoprotein in the shape of the nephron segment where they were formed. Heavy proteinuria and lipiduria are consistent with the nephrotic syndrome. The presence of hematuria with dysmorphic red blood cells, red blood cell casts, and proteinuria is indicative of glomerulonephritis. Dysmorphic red blood cells are misshapen during abnormal passage from the capillary through the glomerular basement membrane (GBM) into the urinary space of Bowman capsule. Pigmented granular casts and renal tubular epithelial cells alone or in casts suggest acute tubular necrosis. White blood cells, including neutrophils and eosinophils, white blood cell casts (Table 22–1), red blood cells, and small amounts of protein can be found in interstitial nephritis and pyelonephritis; Wright and Hansel stains can detect eosinophiluria. Pyuria alone can indicate a urinary tract infection. Hematuria and proteinuria are discussed more thoroughly below.

#### A. Proteinuria

Proteinuria is defined as excessive protein excretion in the urine, generally > 150–160 mg/24 h in adults. Significant proteinuria is a sign of an underlying kidney abnormality, usually glomerular in origin when > 1 g/d to < 2 g/d. Less than 1 g/d can be due to multiple causes along the nephron segment, as listed below. Proteinuria can be accompanied by other clinical abnormalities—elevated blood urea nitrogen (BUN) and serum creatinine levels, abnormal urinary sediment, or evidence of systemic illness (eg, fever, rash, vasculitis).

There are several reasons for development of proteinuria: (1) **Functional proteinuria** is a benign process stemming from stressors such as acute illness, exercise, and
increased permeability of albumin across a damaged GBM.

Transport of normally filtered proteins in the proximal tubule, such as β₂-microglobulin and immunoglobulin light chains. Causes include acute tubular necrosis, toxic injury (lead, aminoglycosides), drug-induced interstitial nephritis, and hereditary metabolic disorders (Wilson disease and Fanconi syndrome).

Evaluation of proteinuria by urinary dipstick primarily detects albumin, while over-looking positively charged light chains of immunoglobulins. These proteins can be detected by the addition of sulfosalicylic acid to the urine specimen. Precipitation without dipstick detection of albumin indicates the presence of paraproteins.

The next step is an estimation of proteinuria from a 24-hour urine collection. A finding of > 150–160 mg/24 h is abnormal, and > 3.5 g/24 h is consistent with nephrotic-range proteinuria. The simplest method is to collect a random urine sample. The ratio of urinary protein concentration to urinary creatinine concentration ([U_{protein}] / [U_{creatinine}]) correlates with 24-hour urine protein collection (< 0.2 is normal and corresponds to excretion of < 200 mg/24 h). The benefit of a urine protein-to-creatinine ratio is the ease of collection and the lack of error from overcollection or undercollection of urine. If a patient has proteinuria with or without loss of kidney function, kidney biopsy may be indicated, particularly if the kidney disease is acute in onset. The clinical consequences of proteinuria are discussed in the section Nephrotic Spectrum Glomerular Diseases below.

**B. Hematuria**

Hematuria is significant if there are more than three red cells per high-power field on at least two occasions. It is usually detected incidentally by the urine dipstick examination or clinically following an episode of macroscopic hematuria. The diagnosis must be confirmed via microscopic examination, as false-positive dipstick tests can be caused by myoglobin, oxidizing agents, beets and rhubarb, hydrochloric acid, and bacteria. Transient hematuria is common, but in patients younger than 40 years, it is less often of clinical significance due to lower concern for malignancy.

Hematuria may be due to renal or extrarenal causes. Extrarenal causes are addressed in Chapters 23 and 39; most worrisome are urologic malignancies. Renal causes account for approximately 10% of cases and are best considered anatomically as glomerular or nonglomerular. The most common extraglomerular sources include cysts, calculi, interstitial nephritis, and renal neoplasia. Glomerular causes include immunoglobulin A (IgA) nephropathy, thin GBM disease, membranoproliferative glomerulonephritis (MPGN), other hereditary glomerular diseases (eg, Alport syndrome), and systemic nephritic syndromes.

Currently, the United States Health Preventive Services Task Force does not recommend screening for hematuria. See Chapter 23 for evaluation of hematuria.

**Estimation of GFR**

The GFR provides a useful index of kidney function at the level of the glomerulus. Patients with kidney disease can have a decreased GFR from any process that causes loss of nephron (and thus glomerular) mass. However, they can also have a normal or increased GFR, either from hyperfiltration at the glomerulus or disease at a different segment of the nephron, interstitium, or vascular supply. The GFR measures the amount of plasma ultrafiltered across the glomerular capillaries and correlates with the ability of the kidneys to filter fluids and various substances. Daily GFR in normal individuals is variable, with a range of 150–250 L/24 h or 100–120 mL/min/1.73 m² of body surface area. GFR can be measured indirectly by determining the renal clearance of plasma substances that are not bound to plasma proteins, are freely filterable across the glomerulus, and are neither secreted nor reabsorbed along the renal tubules. The formula used to determine the renal clearance of a substance is

\[
C = \frac{U \times V}{P}
\]

where C is the clearance, U and P are the urine and plasma concentrations of the substance (mg/dL), and V is the urine
flow rate (mL/min). In clinical practice, the clearance rate of endogenous creatinine, the creatinine clearance, is one way of estimating GFR. Creatinine is a product of muscle metabolism produced at a relatively constant rate and cleared by renal excretion. It is freely filterable by the glomerulus and not reabsorbed by the renal tubules. With stable kidney function, creatinine production and excretion are equal; thus, plasma creatinine concentrations remain constant. However, it is not a perfect indicator of GFR for the following reasons: (1) A small amount is normally eliminated by tubular secretion, and the fraction secreted progressively increases as GFR declines (overestimating GFR); (2) with severe kidney failure, gut microorganisms degrade creatinine; (3) an individual’s meat intake and muscle mass affect baseline plasma creatinine levels; (4) commonly used drugs such as aspirin, cimetidine, probenecid, and trimethoprim reduce tubular secretion of creatinine, increasing the plasma creatinine concentration and falsely indicating kidney dysfunction; and (5) the accuracy of the measurement necessitates a stable plasma creatinine concentration over a 24-hour period, so that during the development of and recovery from acute kidney injury, when the serum creatinine is changing, the creatinine clearance is of questionable value (Table 22–2). Of note, the creatinine clearance is the traditional estimation equation used for consideration of drug dosing in patients with kidney disease.

One way to measure creatinine clearance is to collect a timed urine sample and determine the plasma creatinine level midway through the collection. An incomplete or prolonged urine collection is a common source of error. One way of estimating the completeness of the collection is to calculate a 24-hour creatinine excretion; the amount should be constant:

\[
U_c \times V = 15-20 \text{ mg/kg for healthy young women}
\]

\[
U_c \times V = 20-25 \text{ mg/kg for healthy young men}
\]

The creatinine clearance (Ccr) is approximately 100 mL/min/1.73 m² in healthy young women and 120 mL/min/1.73 m² in healthy young men. The Ccr declines by an average of 0.8 mL/min/yr after age 40 years as part of the aging process, but 35% of subjects in one study had no decline in kidney function over 10 years.

Ccr can be estimated from the formula of Cockcroft and Gault, which incorporates age, sex, and weight to estimate Ccr from plasma creatinine levels without any urinary measurements:

\[
Ccr = \frac{(140 - \text{Age}) \times \text{Weight (kg)}}{72 \times \text{Pcr}}
\]

For women, the creatinine clearance is multiplied by 0.85 because muscle mass is less. This formula overestimates GFR in patients who are obese or edematous and is most accurate when normalized for body surface area of 1.73 m².

BUN is another index used in assessing kidney function. It is synthesized mainly in the liver and is the end product of protein catabolism. Urea is freely filtered by the glomerulus, and about 30–70% is reabsorbed in the renal tubules. Unlike creatinine clearance, which overestimates GFR, urea clearance underestimates GFR. Urea reabsorption may be decreased in volume replete patients, whereas volume depletion causes increased urea reabsorption, in conjunction with increased sodium reabsorption, from the kidney, increasing BUN. A normal BUN:creatinine ratio is 10:1, although this can vary between individuals. With volume depletion, the ratio can increase to 20:1 or higher. Other causes of increased BUN include increased catabolism (gastrointestinal [GI] bleeding, cell lysis, and corticosteroid usage), increased dietary protein, and decreased renal perfusion (congestive heart failure, renal artery stenosis) (Table 22–3). Reduced BUN is seen in liver disease and in the syndrome of inappropriate antidiuretic hormone (SIADH) secretion.

As patients approach end-stage renal disease (ESRD), a more accurate measure of GFR than creatinine clearance is the average of the creatinine and urea clearances. The creatinine clearance overestimates GFR, as mentioned above, while the urea clearance underestimates GFR. Therefore, an average of the two more accurately approximates the true GFR.

The four-variable estimated GFR is a complex equation, including serum creatinine, age, weight, and race, that is often reported alongside serum creatinine measurements.

and more accurate than creatinine or urea clearance. This was derived from data collected for the Modification of Diet and Renal Disease (MDRD) study and has been validated in several other populations. Many laboratories will report a value for the estimated GFR in addition to a serum creatinine. Several web-based calculators will calculate this; one location is www.nephron.com.

Other useful, well-validated estimators of GFR include the CKD-EPI formula. This is more accurate and precise than the MDRD equation at higher levels of true GFR, possibly decreasing false-positive results. This formula may perform better in elderly populations; however, this estimation did not include large numbers of nonwhite patients.

Cystatin C is another endogenous marker of GFR, filtered freely at the glomerulus and produced at a relatively constant rate, irrespective of muscle mass. It is reabsorbed and partially metabolized in the renal tubular epithelial cells. Studies show less variability with age, gender, or race for cystatin C versus serum creatinine.

RENALE BIOPSY

Indications for percutaneous needle biopsy include (1) unexplained acute kidney injury or CKD; (2) acute nephritic syndromes; (3) unexplained proteinuria and hematuria; (4) previously identified and treated lesions to plan future therapy; (5) systemic diseases associated with kidney dysfunction, such as systemic lupus erythematosus, Goodpasture syndrome, and granulomatosis with polyangiitis (formerly Wegener granulomatosis), to confirm the extent of renal involvement and to guide management; (6) suspected transplant rejection, to differentiate it from other causes of acute kidney injury; and (7) to guide treatment. If a patient is unwilling to accept therapy based on biopsy findings, the risk of biopsy may outweigh its benefit. Relative contraindications include a solitary or ectopic kidney (exception: transplant allografts), horseshoe kidney, ESRD, congenital anomalies, and multiple cysts. Absolute contraindications include an uncorrected bleeding disorder, severe uncontrollable hypertension, renal infection, renal neoplasm, hydrenephrosis, or an uncooperative patient.

Prior to biopsy, patients should not use medications that prolong clotting times and should have well-controlled blood pressure. Blood work should include a hemoglobin, platelet count, prothrombin time, and partial thromboplastin time. After biopsy, hematuria occurs in nearly all patients. Less than 10% will have macroscopic hematuria. Patients should remain supine for 4–6 hours postbiopsy. A patient with a 6-hour postbiopsy hematocrit >3% lower than baseline should be closely monitored.

Percutaneous kidney biopsies are generally safe. Approximately 1% of patients will experience significant bleeding requiring blood transfusions. More than half of patients will have at least a small hematoma. Risk of major bleeding persists up to 72 hours after the biopsy. Any type of anticoagulation therapy should be held for 5–7 days postbiopsy if possible. The risks of nephrectomy and mortality are about 0.06–0.08%. When a percutaneous needle biopsy is technically not feasible and renal tissue is deemed clinically essential, a closed renal biopsy via interventional radiologic techniques or open renal biopsy under general anesthesia can be done.

Stevens LA et al. Comparative performance of the CKD Epidemiology Collaboration (CKD-EPI) and the Modification of Diet in Renal Disease (MDRD) Study equations for estimating GFR levels above 60 mL/min/1.73 m2. Am J Kidney Dis. 2010 Sep;56(3):486–95. [PMID: 20557989]

ACUTE KIDNEY INJURY (ACUTE RENAL FAILURE)

ESSENTIALS OF DIAGNOSIS

- Sudden increase in BUN or serum creatinine.
- Oliguria can be associated.
- Symptoms and signs depend on cause.

General Considerations

Acute kidney injury, also known as acute renal failure, is defined as a sudden decrease in kidney function, resulting in an inability to maintain acid-base, fluid and electrolyte balance and to excrete nitrogenous wastes. Serum creatinine is a convenient marker. A clinically applicable definition of acute kidney injury has been developed. The RIFLE criteria describe three progressive levels of acute kidney injury (risk, injury, and failure) based on the elevation in serum creatinine or decline in urinary output with two outcome measures (loss and ESRD). Risk, injury, and failure are defined, respectively, as a 1.5-fold increase in serum creatinine, a twofold or threefold increase in serum creatinine, or a decline in urinary output to 0.5 mL/kg/h over 6, 12, or 24 hours. These definitions were created by an international consensus panel and correlate with prognosis. The AKIN criteria are also predictive of outcomes, and closely follow the RIFLE criteria, with the addition of a change in serum creatinine of ≥0.3 mg/day qualifying as a risk for injury. In the absence of functioning kidneys, serum creatinine concentration will typically increase by 1–1.5 mg/dL daily, although with certain conditions, such as rhabdomyolysis, serum creatinine can increase more rapidly. On average, 5% of hospital admissions and 30% of intensive care unit (ICU) admissions carry a diagnosis of acute kidney injury, and it will develop in 25% of hospitalized patients. Patients with
Acute kidney injury of any type are at higher risk for all-cause mortality according to recent prospective cohorts, whether or not there is substantial renal recovery.

**Clinical Findings**

**A. Symptoms and Signs**

The uremic milieu of acute kidney injury can cause nonspecific symptoms. When present, symptoms are often due to uremia or its underlying cause. Uremia can cause nausea, vomiting, malaise, and altered sensorium. Hypertension can occur, and fluid homeostasis is often altered. Hypovolemia can cause states of low blood flow to the kidneys, sometimes termed “prerenal” states, whereas hypervolemia can result from intrinsic or “postrenal” disease. Pericardial effusions can occur with uremia, and a pericardial friction rub can be present. Effusions may result in cardiac tamponade. Arrhythmias occur, especially with hyperkalemia. The lung examination may show rales in the presence of hypervolemia. Acute kidney failure can cause nonspecific diffuse abdominal pain and ileus as well as platelet dysfunction; thus, bleeding and clotting disorders are more common in these patients. The neurologic examination reveals encephalopathic changes with asterixis and confusion; seizures may ensue.

**B. Laboratory Findings**

Elevated BUN and serum creatinine levels are present, though these elevations do not distinguish acute kidney disease from CKD. Hyperkalemia can occur from impaired renal potassium excretion. With hyperkalemia, the ECG can reveal peaked T waves, PR prolongation, and QRS widening. A long QT segment can occur with hypocalcemia. Anion gap and non-gap metabolic acidosis (due to decreased organic and nonorganic acid clearance) is often noted. Hyperphosphatemia occurs when phosphorus cannot be secreted by damaged tubules either with or without increased cell catabolism. Metastatic calcium phosphate deposition may be observed when the product of calcium and phosphorus is elevated (eg, exceeding 55–65 mg²/dL²). Anemia can occur as a result of decreased erythropoietin production over weeks, and associated platelet dysfunction is typical.

**Classification & Etiology**

Acute kidney injury can be divided into three categories: prerenal causes (renal hypoperfusion leading to lower GFR), intrinsic renal disease, and postrenal causes (obstructive uropathy). Identifying the cause is the first step toward treating the patient (Table 22–4).

**A. Prerenal Causes**

Prerenal causes are the most common reason for acute kidney insults and injury, accounting for 40–80% of cases, depending on the population studied. Prerenal azotemia is due to renal hypoperfusion, which is an appropriate physiologic change. If it can be immediately reversed with restoration of renal blood flow, renal parenchymal damage often does not occur. If hypoperfusion persists, ischemia can result, causing intrinsic kidney injury.

Decreased renal perfusion can occur in several ways, such as a decrease in intravascular volume, a change in vascular resistance, or low cardiac output. Causes of volume depletion include hemorrhage, GI losses, dehydration, excessive diuresis, extravascular space sequestration, pancreatitis, burns, trauma, and peritonitis.

Changes in vascular resistance can occur systemically with sepsis, anaphylaxis, anesthesia, and afterload-reducing drugs. Blockers of the renin-angiotensin-aldosterone system, such as angiotensin-converting enzyme (ACE) inhibitors, prevent efferent renal arteriolar constriction out of

| Table 22–4. Classification and differential diagnosis of acute kidney injury. |

| **Etiology**                     | **Prerenal Azotemia**           | **Postrenal Azotemia**        | **Intrinsic Renal Disease**   |
| Etiology                         | Poor renal perfusion            | Obstruction of the urinary tract | Ischemia, nephrotoxins        |
| Serum BUN-Cr ratio               | > 20:1                          | > 20:1                        | < 20:1                        |
| Urinary indices                  |                                |                               | > 20:1                        |
| Urinary index                    |                                |                               | < 20:1                        |
| Uni Na, (mEq/L)                  | < 20                            | Variable                      | > 20                          |
| Fr Na (%)                        | < 1                             | Variable                      | < 20                          |
| Urine osmolality, (mosm/kg)      | > 500                           | Variable                      | < 1                           |
| Urinary sediment                 | Benign or hyaline casts         | Normal or red cells, white cells, or crystals | Granular (muddy brown) casts, renal tubular casts |
|                                  |                                |                               | Red cells, dysmorphic red cells and red cell casts |
|                                  |                                |                               | White cells, white cell casts, with or without eosinophils |

BUN-Cr, blood urea nitrogen:creatinine ratio; Fr Na, fractional excretion of sodium; Uni Na, urinary concentration of sodium.
proportion to the afferent arteriolar constriction; thus, GFR will decrease with these medications. Nonsteroidal anti-inflammatory drugs (NSAIDs) prevent afferent arteriolar vasodilation by inhibiting prostaglandin-mediated signals. Thus, in cirrhosis and congestive heart failure, when prostaglandins are recruited to increase renal blood flow, NSAIDs will have particularly deleterious effects. Epinephrine, norepinephrine, high-dose dopamine, anesthetic agents, and cyclosporine also can cause renal vasoconstriction. Renal artery stenosis causes increased resistance and decreased renal perfusion.

Low cardiac output is a state of low effective renal arterial blood flow. This occurs in states of cardiogenic shock, congestive heart failure, pulmonary embolism, and pericardial tamponade. Arrhythmias and valvular disorders can also reduce cardiac output. In the ICU setting, positive pressure ventilation will decrease venous return, also decreasing cardiac output.

When GFR falls acutely, it is important to determine whether acute kidney injury is due to prerenal or intrinsic renal causes. The history and physical examination are important, and urinalysis can be helpful. The BUN:creatinine ratio will typically exceed 20:1 due to increased urea reabsorption. In an oliguric patient, another useful index is the fractional excretion of sodium,

\[
\text{F}_{\text{ENO}} = \frac{\text{Na}_{\text{U}} \times \text{S}_{\text{U}} - \text{Na}_{\text{S}} \times \text{S}_{\text{S}}}{\text{Na}_{\text{S}} \times \text{S}_{\text{U}}} 	imes 100
\]

renal sodium handling is more accurately assessed by the fractional excretion of sodium (\(\text{F}_{\text{ENO}}\)). With decreased GFR, the kidney will reabsorb salt and water avidly if there is no intrinsic tubular dysfunction. Thus, patients with prerenal causes should have a low fractional excretion percent of sodium (<1%). Oliguric patients with intrinsic kidney dysfunction typically have a high fractional excretion of sodium (1–2%). The \(\text{F}_{\text{ENO}}\) is calculated as follows:

\[
\text{F}_{\text{ENO}} = \frac{\text{clearance of } \text{Na}^+}{\text{GFR}} \times \text{clearance of } \text{Na}^+/	ext{Cr}^+
\]

Renal sodium handling is more accurately assessed by the fractional excretion of sodium in oliguric states than in nonoliguric states because the fractional excretion of sodium can be relatively low in nonoliguric acute tubular necrosis if sodium intake and excretion are relatively low. Oliguria is defined as urinary output <400–500 mL/d, or <20 mL/h. Diuretics can cause increased sodium excretion. Thus, if the \(\text{F}_{\text{ENO}}\) is high within 12–24 hours after diuretic administration, the cause of acute kidney injury may not be accurately predicted. Acute kidney injury due to glomerulonephritis can have a low \(\text{F}_{\text{ENO}}\) because sodium reabsorption and tubular function may not be compromised.

Treatment of prerenal insults depends entirely on the causes, but maintenance of euolemia attention to serum potassium, and avoidance of nephrotoxic drugs are benchmarks of therapy. This involves careful assessment of volume status, cardiac function, diet, and drug usage.

**B. Postrenal Causes**

Postrenal causes are the least common reason for acute kidney injury, accounting for approximately 5–10% of cases, but important to detect because of their reversibility. Postrenal azotemia occurs when urinary flow from both kidneys, or a single functioning kidney, is obstructed. Occasionally, postrenal uropathies can occur when a single kidney is obstructed if the contralateral kidney cannot adjust for the loss in function, (eg, in a patient with advanced CKD). Obstruction leads to elevated intraluminal pressure, causing kidney parenchymal damage, with marked effects on renal blood flow and tubular function, and a decrease in GFR.

Postrenal causes include urethral obstruction, bladder dysfunction or obstruction, and obstruction of both ureters or renal pelvises. Men with benign prostatic hyperplasia is the most common cause. Patients taking anticholinergic drugs are particularly at risk. Obstruction can also be caused by bladder, prostate, and cervical cancers; retroperitoneal fibrosis and other processes; and neurogenic bladder. Less common causes are blood clots, bilateral ureteral stones, urethral stones or stricture, and bilateral papillary necrosis.

Patients may be anuric or polyuric and may complain of lower abdominal pain. Polyuria can occur in the setting of partial obstructions with resultant tubular dysfunction and an inability to appropriately reabsorb salt and water loads. Obstruction can be constant or intermittent and partial or complete. On examination, the patient may have an enlarged prostate, distended bladder, or mass detected on pelvic examination.

Laboratory examination may initially reveal high urine osmolality, low urine sodium, high BUN:creatinine ratio, and low \(\text{F}_{\text{ENO}}\) (as tubular function may not be compromised initially). These indices are similar to a prerenal picture because extensive intrinsic renal damage has not occurred. After several days, the urine sodium increases as the kidneys fail and are unable to concentrate the urine—thus, isosthenuria is present. The urine sediment is generally benign.

Patients with acute kidney injury and suspected postrenal insults should undergo bladder catheterization and ultrasonography to assess for hydroureretr and hydronephrosis. After reversal of the underlying process, these patients often undergo a postobstructive saliuresis and diuresis, and care should be taken to avoid volume depletion. Rarely, obstruction is not diagnosed by ultrasonography. For example, patients with retroperitoneal fibrosis from tumor or radiation may not show dilataion of the urinary tract. If suspicion does exist, a CT scan or MRI can establish the diagnosis. Prompt treatment of obstruction within days by catheters, stents, or other surgical procedures can result in partial or complete reversal of the acute process.

**C. Intrinsic Acute Kidney Injury**

Intrinsic renal disorders account for up to 50% of all cases of acute kidney injury. Intrinsic dysfunction is considered after prerenal and postrenal causes have been excluded. The sites of injury are the tubules, interstitium, vasculature, and glomeruli.

**When to Refer**

- If a patient has signs of acute kidney injury that have not reversed over 1–2 weeks, but no signs of acute uremia, the patient can usually be referred to a nephrologist rather than admitted.
- If a patient has signs of persistent urinary tract obstruction, the patient should be referred to a urologist.
When to Admit

The patient should be admitted if there is sudden loss of kidney function resulting in abnormalities that cannot be handled expeditiously in an outpatient setting (eg, hyperkalemia, volume overload, uremia) or other requirements for acute intervention, such as emergent urologic intervention or dialysis.

ACUTE TUBULAR NECROSIS

ESSENTIALS OF DIAGNOSIS

- Acute kidney injury.
- Ischemic or toxic insult.
- Urine sediment with pigmented granular casts and renal tubular epithelial cells is pathognomonic but not essential.

General Considerations

Acute kidney injury due to tubular damage is termed “acute tubular necrosis” and accounts for approximately 85% of intrinsic acute kidney injury. The two major causes of acute tubular necrosis are ischemia and nephrotoxin exposure. Ischemia causes tubular damage from states of prolonged low kidney perfusion, often termed a “prerenal” state, with resultant tubular necrosis and apoptosis. Ischemic acute kidney injury is characterized not only by inadequate GFR but also by renal blood flow inadequate to maintain parenchymal cellular formation. This occurs in the setting of prolonged hypotension or hypoxemia, such as volume depletion, shock, and sepsis. Major surgical procedures can involve prolonged periods of hypoperfusion, which are exacerbated by vasodilating anesthetic agents. Aside from the serum creatinine, other urinary and serum biomarkers, including neutrophil gelatinase-associated lipocalin and cystatin C, are being investigated in order to diagnose and treat acute kidney injury earlier in its course, with the potential for better outcomes.

Exogenous nephrotoxins more commonly cause damage than endogenous nephrotoxins.

A. Exogenous Nephrotoxins

Aminoglycosides cause some degree of acute tubular necrosis in up to 25% of hospitalized patients receiving therapeutic levels of the drugs. Nonoliguric kidney injury typically starts to occur after 5–10 days of exposure. Predisposing factors include underlying kidney damage, volume depletion, and advanced age. Aminoglycosides can remain in renal tissues for up to a month, so kidney function may not recover for some time after stopping the medication. Monitoring of peak and trough levels is important, but trough levels are more helpful in predicting renal toxicity. Gentamicin is as nephrotoxic as tobramycin; streptomycin is the least nephrotoxic of the aminoglycosides, likely due to the number of cationic amino side chains present on each molecule.

Amphotericin B is typically nephrotoxic after a dose of 2–3 g. This causes a type I renal tubular acidosis with severe vasoconstriction and distal tubular damage, which can lead to hypokalemia and nephrogenic diabetes insipidus. Vancomycin, intravenous acyclovir, and several cephalosporins have been known to cause acute tubular necrosis.

Radiographic contrast media may be directly nephrotoxic. Contrast nephropathy is the third leading cause of new acute kidney injury in hospitalized patients. It probably results from the synergistic combination of direct renal tubular epithelial cell toxicity and renal medullary ischemia. Predisposing factors include advanced age, preexisting kidney disease (serum creatinine >2 mg/dL), volume depletion, diabetic nephropathy, congestive heart failure, multiple myeloma, repeated doses of contrast, and recent exposure to other nephrotoxic agents, including NSAIDs and ACE inhibitors. The combination of preexisting diabetes mellitus and kidney dysfunction poses the greatest risk (15–50%) for contrast nephropathy. Lower volumes of contrast with lower osmolality are recommended in high-risk patients. Toxicity usually occurs within 24–48 hours after the radiographic contrast study. Nonionic contrast media may be less toxic, but this has not been well proven. Prevention should be the goal when using these agents. The mainstay of therapy is a liter of intravenous 0.9% saline over 10–12 hours both before and after the contrast administration—cautiously in patients with preexisting cardiac dysfunction. Neither mannitol nor furosemide offers benefit over 0.9% (normal) saline administration. In fact, furosemide may lead to increased rates of renal dysfunction in this setting. In some but not all studies, N-acetylcysteine given before and after contrast decreases the incidence of dye-induced nephrotoxicity. Acetylcysteine is a thiol-containing antioxidant with little toxicity whose mechanism of action is unclear. It is rarely given unless a patient has a preexisting risk factor. With little harm and possible benefit, administering acetylcysteine 600 mg orally every 12 hours twice, before and after a dye load, for patients at risk for acute kidney injury, is a reasonable strategy. Intravenous N-acetylcysteine, 1200 mg prior to an emergent procedure, has shown benefit compared with placebo and may be a good option if a patient needs contrast dye urgently. One large prospective randomized controlled trial showed no benefit of N-acetylcysteine in over 2300 patients randomized to either 1200 mg orally twice versus placebo prior to and after angiographic procedures. The primary endpoint was a 25% increase in serum creatinine within 48–96 hours after the procedure. Some
investigators have shown a benefit using sodium bicarbonate (154 mEq/L, intravenously at 3 mL/kg/h for 1 hour before the procedure, then 1 mL/kg/h for 6 hours after the procedure) over a more conventional regimen of normal saline as the isotonic volume expander. However, others have shown sodium bicarbonate was not superior to sodium chloride when using similar administration regimens. Other nephrotoxic agents should be avoided during the day before and after dye administration.

**Cyclosporine** toxicity is usually dose dependent. It causes distal tubular dysfunction (a type 4 renal tubular acidosis) from severe vasoconstriction. Regular blood level monitoring is important to prevent both acute and chronic nephrotoxicity. With patients who are taking cyclosporine for renal transplant rejection, kidney biopsy is often necessary to distinguish transplant rejection from cyclosporine toxicity. Renal function usually improves after reducing the dose or stopping the drug.

Other exogenous nephrotoxins include antineoplastics, such as cisplatin and organic solvents, and heavy metals such as mercury, cadmium, and arsenic.

**B. Endogenous Nephrotoxins**

Endogenous nephrotoxins include heme-containing products, uric acid, and paraproteins. **Myoglobinuria** as a consequence of rhabdomyolysis leads to acute tubular necrosis. Necrotic muscle releases large amounts of myoglobin, which is freely filtered across the glomerulus. The myoglobin is reabsorbed by the renal tubules, and direct damage can occur. Distal tubular obstruction from pigmented casts and intrarenal vasoconstriction can also cause damage. This type of kidney injury occurs in the setting of crush injury, or muscle necrosis from prolonged unconsciousness, seizures, cocaine, and alcohol abuse. Dehydration and acidosis predispose to the development of myoglobinuric acute kidney injury. Patients may complain of muscular pain and often have signs of muscle injury. Rhabdomyolysis of clinical importance commonly occurs with a serum creatine kinase (CK) > 20,000–50,000 international units/L. One study showed that 58% of patients with acute kidney injury from rhabdomyolysis had CK levels > 16,000 international units/L. Only 11% of patients without kidney injury had CK values > 16,000 international units/L. The globin moiety of myoglobin will cause the urine dipstick to read falsely positive for hemoglobin: the urine appears dark brown, but no red cells are present. With lysis of muscle cells, patients also become hyperkalemic, hyperphosphatemic, and hyperuricemic. Hypocalcemia may ensue due to phosphorus and calcium precipitation. The mainstay of treatment is volume repletion. Other adjunctive treatments include mannitol for free radical clearance and diuresis as well as alkalinization of the urine. These modalities have not been proved to change outcomes in human trials. Hypocalcemia should not be treated unless the patient is symptomatic. As the patient recovers, calcium can move back from tissues to plasma, so early exogenous calcium administration is not recommended unless the patient has symptoms or the level becomes exceedingly low in an unconscious patient because such repletion could result in hypercalcemia later in the course of the illness.

**Hemoglobin** can cause a similar form of acute tubular necrosis. Massive intravascular hemolysis is seen in transfusion reactions and in certain hemolytic anemias. Reversal of the underlying disorder and hydration are the mainstays of treatment.

**Hyperuricemia** can occur in the setting of rapid cell turnover and lysis. Chemotherapy for germ cell neoplasms and leukemia and lymphoma are the primary causes. Acute kidney injury occurs with intratubular deposition of uric acid crystals; serum uric acid levels are often > 15–20 mg/dL and urine uric acid levels > 600 mg/24 h. A urine uric acid to urine creatinine ratio > 1.0 indicates risk of acute kidney injury.

**Bence Jones protein** seen in conjunction with multiple myeloma can cause direct tubular toxicity and tubular obstruction. Other renal complications from multiple myeloma include hypercalcemia and renal tubular dysfunction, including proximal renal tubular acidosis (see Multiple Myeloma, below).

**Clinical Findings**

**A. Symptoms and Signs**

See Acute Kidney Injury.

**B. Laboratory Findings**

Hyperkalemia and hyperphosphatemia are commonly encountered. BUN:creatinine ratio is usually < 20:1 because tubular function is not intact, per the mechanisms described in the general section on acute kidney injury (Table 22–4). Urinalysis may show evidence of acute tubular damage. The urine may be brown. Urinary output can be either oliguric or nonoliguric, with oliguria portending a worse prognosis. Urine sodium concentration is typically elevated, but the FeNa is more indicative of tubular function, as discussed above. On microscopic examination, an active sediment may show pigmented granular casts or “muddy brown” casts. Renal tubular epithelial cells and epithelial cell casts can be present (see Table 22–1).

**Treatment**

Treatment is aimed at hastening recovery and avoiding complications. Preventive measures should be taken to avoid volume overload and hyperkalemia. Loop diuretics have been used in large doses (eg, furosemide in doses ranging from 20 mg to 160 mg orally or intravenously twice daily, or as a continuous infusion) to affect adequate diuresis and may help convert oliguric to nonoliguric renal failure. Such a conversion has never been shown to affect outcomes such as mortality, though. One retrospective study has shown potentially worse outcomes in patients who receive doses of furosemide, including non-recovery of renal function and an increased risk of death. A prospective randomized controlled trial has shown no difference between the administration of large doses of diuretics versus placebo on either recovery from acute kidney injury or death. Widespread use of diuretics in
Critically ill patients with acute kidney injury should thus be discouraged. Disabling side effects of supranormal dosing include hearing loss and cerebellar dysfunction. This is mainly due to peak furosemide levels; this risk can be minimized by the use of a furosemide drip. A starting dose of 0.1–0.3 mg/kg/h is appropriate, increasing to a maximum of 0.5–1 mg/kg/h. A bolus of 1–1.5 mg/kg should be administered at the beginning of each dose escalation. Intravenous thiazide diuretics can be used to augment urinary output; chlorothiazide, 250–500 mg intravenously every 8–12 hours, is a reasonable choice. Another good choice to augment diuresis is metolazone at doses of 2.5–5 mg given orally once to twice daily, 30 minutes prior to loop diuretics. It is less expensive than intravenous chlorothiazide and has reasonable bioavailability. Short-term effects of loop diuretics include activation of the renin–angiotensin system. One prospective randomized trial showed the long-term benefits of plasma ultrafiltration over the use of intravenous diuretics in patients with decompensated heart failure. This intervention can be considered in ICU patients with acute kidney injury in need of volume removal who are nonresponsive to diuretics. Nutritional support should maintain adequate intake while preventing excessive catabolism. Dietary protein restriction of 0.6 g/kg/d helps prevent metabolic acidosis. Hypocalcemia and hyperphosphatemia can be improved with diet and phosphate-binding agents, such as aluminum hydroxide (500 mg orally with meals) over the short term, and calcium carbonate (500–1500 mg orally three times daily), calcium acetate (667 mg, two or three tablets, orally before meals), sevelamer carbonate (800–1600 mg orally three times daily), and lanthanum carbonate (1000 mg orally with meals) over longer periods. Hypocalcemia should not be treated in patients with rhabdomyolysis unless they are symptomatic. Hypermagnesemia can occur because of reduced magnesium excretion by the renal tubules, so magnesium-containing antacids and laxatives should be avoided in these patients. Dosages of all medications must be adjusted according to the estimated degree of renal impairment for drugs eliminated by the kidney.

Indications for dialysis in acute kidney injury from acute tubular necrosis or other intrinsic disorders include life-threatening electrolyte disturbances (such as hyperkalemia), volume overload unresponsive to diuresis, worsening acidosis, and uremic complications (eg, encephalopathy, pericarditis, and seizures). In gravely ill patients, less severe but worsening abnormalities may also be indications for dialytic support. Two prospective randomized control trials, each with more than 1100 patients, showed that an intensive dialysis dose was not superior to a more conventional dose.

**Course & Prognosis**

The clinical course of acute tubular necrosis is often divided into three phases: initial injury, maintenance, and recovery. The maintenance phase is expressed as either oliguric (urinary output < 500 mL/d) or nonoliguric. Nonoliguric acute tubular necrosis has a better outcome. Conversion from oliguric to nonoliguric states may be attempted but has not been shown to change the prognosis. Drugs such as dopamine and diuretics are sometimes used for this purpose but have not been shown to improve outcomes. In numerous studies, dopamine use in this setting has no benefit. Average duration of the maintenance phase is 1–3 weeks but may be several months. Cellular repair and removal of tubular debris occur during this period. The recovery phase can be heralded by diuresis. GFR begins to rise; BUN and serum creatinine fall.

The mortality rate associated with acute kidney injury is 20–50% in hospitalized settings, and up to 70% with additional comorbid illnesses. Increased mortality is associated with advanced age, severe underlying disease, and multisystem organ failure. Leading causes of death are infections, fluid and electrolyte disturbances, and worsening of underlying disease. Mortality rates may be starting to improve slightly according to two retrospective cohort studies conducted within the last 10 years.

**When to Refer**

- A patient with acute tubular necrosis should be referred to a nephrologist when the etiology is unclear or renal function continues to worsen despite intervention.
- Also, referral is appropriate if fluid, electrolyte, and acid-base abnormalities are recalcitrant to interventions.
- Studies have shown that nephrology referral improves outcome in acute kidney injury.

**When to Admit**

Admission is appropriate when a patient has symptoms or signs of acute kidney injury that require immediate intervention, such as intravenous fluids, dialytic therapy, or that requires a team approach that cannot be coordinated as an outpatient.

**INTERSTITIAL NEPHRITIS**

**ESSENTIALS OF DIAGNOSIS**

- Fever.
- Transient maculopapular rash.
- Acute or chronic kidney injury.
- Pyuria (including eosinophiluria), white blood cell casts, and hematuria.

**General Considerations**

Acute interstitial nephritis accounts for 10–15% of cases of intrinsic renal failure. An interstitial inflammatory response with edema and possible tubular cell damage is the typical pathologic finding. Cell-mediated immune reactions prevail over humoral responses. T lymphocytes can cause direct cytotoxicity or release lymphokines that recruit monocytes and inflammatory cells.

Although drugs account for over 70% of cases, acute interstitial nephritis also occurs in infectious diseases, immunologic disorders, or as an idiopathic condition. The most common drugs are penicillins and cephalosporins,
sulfonamides and sulfonamide-containing diuretics, NSAIDs, rifampin, phenytoin, and allopurinol. Proton pump inhibitors have also been recognized as a cause of acute interstitial nephritis. Infectious causes include streptococcal infections, leptospirosis, cytomegalovirus, histoplasmosis, and Rocky Mountain spotted fever. Immunologic entities are more commonly associated with glomerulonephritis, but systemic lupus erythematosus, Sjögren syndrome, sarcoidosis, and cryoglobulinemia can cause interstitial nephritis.

**Clinical Findings**

Clinical features can include fever (>80%), rash (25–50%), arthralgias, and peripheral blood eosinophilia (80%). The classic triad of fever, rash, and arthralgias is present in only 10–15% of cases. The urine often contains red cells (95%), white cells, and white cell casts. Proteinuria can be a feature, particularly in NSAID-induced interstitial nephritis, but is usually modest (<2 g/24 h). Eosinophilia is neither very sensitive nor specific and can be detected by Wright or Hansel stain.

**Treatment & Prognosis**

Acute interstitial nephritis often carries a good prognosis. Recovery occurs over weeks to months, but urgent dialytic therapy may be necessary in up to one-third of all referred patients before resolution. Patients rarely progress to ESRD. Those with prolonged courses of oliguric failure and advanced age have a worse prognosis. Treatment consists of supportive measures and removal of the inciting agent. If kidney injury persists after these steps, a short course of corticosteroids can be given, although the data to support use of corticosteroids are not substantial. Short-term, high-dose methylprednisolone (0.5–1 g/d intravenously for 1–4 days) or prednisone (60 mg/d orally for 1–2 weeks) followed by a prednisone taper can be used in these more severe cases of drug-induced interstitial nephritis.

**Glomerulonephritis**

**Clinical Findings**

- Hematuria, dysmorphic red cells, red cell casts, and mild proteinuria.
- Dependent edema and hypertension.
- Acute renal insufficiency.

**General Considerations**

Acute glomerulonephritis is a relatively uncommon cause of acute kidney injury, accounting for about 5% of cases. Pathologically, inflammatory glomerular lesions are seen. These include mesangioproliferative, focal and diffuse proliferative, and crescentic lesions. The larger the percentage of glomeruli involved and the more severe the lesion, the more likely it is that the patient will have a poor clinical outcome.

Categorization of acute glomerulonephritis can be done by serologic analysis. Markers include anti-GBM antibodies, antineutrophil cytoplasmic antibodies (ANCAs), and other immune markers of disease.

**Immune complex deposition** usually occurs when moderate antigen excess over antibody production occurs. Complexes formed with marked antigen excess tend to remain in the circulation. Antibody excess with large antigen–antibody aggregates usually results in phagocytosis and clearance of the precipitates by the mononuclear phagocytic system in the liver and spleen. Causes include IgA nephropathy (Berger disease), peri-infectious or post-infectious glomerulonephritis, endocarditis, lupus nephritis, cryoglobulinemic glomerulonephritis (often associated with hepatitis C virus), and MPGN.

**Anti-GBM–associated acute glomerulonephritis** is either confined to the kidney or associated with pulmonary hemorrhage. The latter is termed “Goodpasture syndrome.” Injury is related to autoantibodies aimed against type IV collagen in the GBM rather than to immune complex deposition.

**Pauci-immune acute glomerulonephritis** is a form of small-vessel vasculitis associated with ANCAs, causing primary and secondary kidney diseases that do not have direct immune complex deposition or antibody binding. Tissue injury is believed to be due to cell-mediated immune processes. An example is granulomatosis with polyangiitis, a systemic necrotizing vasculitis of small arteries and veins associated with intravascular and extravascular granuloma formation. In addition to glomerulonephritis, these patients can have upper airway, pulmonary, and skin manifestations of disease. Cytoplasmic ANCA (c-ANCA) is a common pattern. Microscopic polyangiitis is another pauci-immune vasculitis causing acute glomerulonephritis. Perinuclear staining (p-ANCA) is the common pattern. ANCA-associated and anti-GBM-associated acute glomerulonephritis can evolve to crescentic glomerulonephritis and often have poor outcomes unless treatment is started early. Both are described more fully below.

**Other vascular causes** of acute glomerulonephritis include hypertensive emergencies and the thrombotic microangiopathies such as hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura (see Chapter 14).
Cultures, renal ultrasound, and occasionally renal biopsy. Antibody titers, cryoglobulins, hepatitis serologies, blood ASO titer, anti-GBM antibody levels, ANCAs, antinuclear renal dysfunction is marked (see Table 22–4). Low unless the renal tubulo-interstitial space is affected, and renal dysfunction is marked (see Table 22–4).

Further tests include complement levels (C3, C4, CH50), ASO titer, anti-GBM antibody levels, ANCAs, antinuclear antibody titers, cryoglobulins, hepatitis serologies, blood cultures, renal ultrasound, and occasionally renal biopsy.

**Treatment**

Depending on the nature and severity of disease, treatment can consist of high-dose corticosteroids and cytotoxic agents such as cyclophosphamide. Plasma exchange can be used in Goodpasture disease and pauci-immune glomerulonephritis as a temporizing measure until chemotherapy can take effect. Treatment and prognosis for specific diseases are discussed more fully below.

**Chronic Kidney Disease**

CKD affects more than 20 million Americans, or one in nine adults. Most are unaware of the condition because they remain asymptomatic until the disease has significantly progressed. The National Kidney Foundation’s staging system helps clinicians formulate practice plans (Table 22–5). Over 70% of cases of late-stage CKD (stage 5 CKD and ESRD) in the United States are due to diabetes mellitus or hypertension. Glomerulonephritis, cystic diseases, and other urologic diseases account for another 12%, and 15% of patients have other or unknown causes (Table 22–6). Recently, genetic polymorphisms of the APOL-1 gene has been shown to be associated with an increased risk of the development of CKD in African Americans.

CKD is rarely reversible and usually leads to a progressive decline in kidney function even after the inciting event has been removed. Destruction of nephrons (inciting event) leads to compensatory hypertrophy of the remaining nephrons, which must increase their individual GFRs to supranormal in order to maintain overall homeostasis. One consequence of this compensatory hyperfiltration is that the serum creatinine may remain relatively normal even in the face of significant loss of renal mass; therefore, it is a relatively insensitive marker for renal damage and scarring. In addition, compensatory hyperfiltration leads to overwork injury in the remaining nephrons, which in turn causes progressive glomerular sclerosis and interstitial fibrosis. Angiotensin receptor blockers (ARBs) and ACE inhibitors can help reduce hyperfiltration injury and are particularly helpful in slowing the progression of proteinuric CKD. Fortunately, an individual’s decreased renal mass as a result of kidney donation is not associated with the development of CKD later in life.

CKD is an independent risk factor for cardiovascular disease; proteinuric CKD confers an even higher risk of cardiovascular mortality.

**General Considerations**

Cardiorenal syndrome is a pathophysiologic disorder of the heart and kidneys wherein the acute or chronic deterioration of one organ results in the acute or chronic deterioration of the other. This syndrome has been classified into five types. Type 1 consists of acute kidney injury stemming from acute cardiac disease. Type 2 is CKD due to chronic cardiac disease. Type 3 is acute cardiac disease as a result of acute kidney injury. Type 4 is chronic cardiac decompensation from CKD. Type 5 consists of heart and kidney dysfunction due to other acute or chronic systemic disorders (such as sepsis). Identifying and defining this common syndrome may assist in the future with treatments to improve its morbidity and mortality.

**Cardiorenal Syndrome**

- **ESSENTIALS OF DIAGNOSIS**
  - Cardiac dysfunction: signs or symptoms of heart failure, ischemic injury or arrhythmias.
  - Kidney disease: acute or chronic, depending on type of cardiorenal syndrome.

- **General Considerations**

Kidney disease

Clinical Findings

A. Symptoms and Signs

In the early stages, CKD is asymptomatic. Symptoms develop slowly with the progressive decline in GFR, are nonspecific, and do not manifest until kidney disease is far advanced (GFR < 10–15 mL/min/1.73 m²). At this point, the build-up of metabolic waste products, or uremic toxins, can result in the uremic syndrome (Table 22–7). General

symptoms of uremia may include fatigue, weakness, and malaise. GI symptoms, such as anorexia, nausea, vomiting, and a metallic taste in the mouth, are common. Neurologic problems may include irritability, difficulty in concentrating, insomnia, subtle memory defects, restless legs, parasthesias, and twitching. Pruritus is common and difficult to treat. Alterations in sexual function, including decreased libido, and menstrual irregularities are common. Chest pain is rare but can occur with pericarditis. Drug toxicity can develop as renal clearance worsens; in particular, hypoglycemia may become problematic, and even life-threatening, in diabetics since insulin is eliminated by the kidneys.

The most common physical finding in CKD is hypertension. It is often present in early stages of CKD and may worsen with CKD progression. The uremic patient (CKD stage 5) appears chronically ill. The skin may be sallow, with easy bruising. Rarely seen in the current era is uremic frost, a cutaneous reflection of ESRD. Uremic fetor is the characteristic fishy odor of the breath. Cardiopulmonary signs may include rales, cardiomegaly, jugular venous distention, edema, and a pericardial friction rub (rarely). Mental status can vary from decreased concentration to confusion, stupor, and coma. Myoclonus and asterixis may be signs of uremia.

Symptoms and signs of uremia warrant immediate hospital admission and nephrology consultation for initiation of dialysis. The uremic syndrome resolves or lessens significantly with dialytic therapy.

In any patient with kidney disease, it is important to identify and correct all possibly reversible insults or exacerbating factors (Table 22–8). Urinary tract infections, obstruction, extracellular fluid volume depletion, hypotension, nephrotoxins (such as NSAIDs), severe or emergent hypertension, and congestive heart failure should be excluded. Any of the above can worsen underlying CKD.

**B. Laboratory Findings**

The diagnosis of CKD is made by documenting elevations of the serum creatinine over at least 3 months. Persistent proteinuria or abnormalities on renal imaging (eg, polycystic kidneys) are also diagnostic of CKD, even when estimated GFR is normal. It is helpful to plot the inverse of serum creatinine ($\frac{1}{S_{Cr}}$) versus time or estimated GFR (if reported by the laboratory) versus time. If three or more prior measurements are available, the time to ESRD can thus be estimated (Figure 22–1). If the slope of the line acutely declines, new and potentially reversible renal insults should be excluded as outlined above. Anemia, hyperphosphatemia, hypocalcemia, hyperkalemia, and metabolic acidosis can occur with both acute kidney disease and CKD. The urinalysis shows isosthenuria if tubular concentrating and diluting ability are impaired. The urinary sediment can show broad waxy casts as a result of dilated, hypertrophic nephrons. Proteinuria may be present. If so, it should be quantified as described above. Quantification of urinary protein is important for several reasons. First, it helps narrow the differential diagnosis of the etiology of the CKD (Table 22–6); for example, glomerular diseases tend to present with protein excretion of > 1 g/d. Second, the presence of proteinuria is associated with more rapid progression of CKD and cardiovascular mortality.

---

Decline in kidney function (expressed as the reciprocal of serum creatinine as shown here, or as estimated glomerular filtration rate [eGFR]) plotted against time to end-stage renal disease (ESRD). The solid line indicates the linear decline in kidney function over time. The dotted line indicates the approximate time to ESRD.](image-url)
C. Imaging

The finding of small echogenic kidneys bilaterally (< 9–10 cm) by ultrasonography supports a diagnosis of CKD, although normal or even large kidneys can be seen with adult polycystic kidney disease, diabetic nephropathy, HIV-associated nephropathy, multiple myeloma, amyloidosis, and obstructive uropathy.

Complications

The complications of CKD tend to occur at relatively predictable stages of disease as noted in Figure 22–2.

A. Cardiovascular Complications

Patients with CKD experience greater morbidity and mortality from cardiovascular disease in comparison to the general population. Death from cardiovascular causes accounts for 45% of all deaths of patients receiving dialysis. Eighty to 90 percent of patients with CKD die, primarily of cardiovascular disease, before reaching need for dialysis. The precise biologic mechanisms for this enhanced mortality are unclear but may have to do with the uremic milieu including abnormal phosphorus and calcium homeostasis, increased burden of oxidative stress, increased vascular reactivity, increased left ventricular hypertrophy, and underlying coexistent comorbidities such as hypertension and diabetes mellitus.

1. Hypertension—Hypertension is the most common complication of CKD. As kidney disease progresses, hypertension due to salt and water retention usually develops. Hyperreninemic states and exogenous erythropoietin administration can also exacerbate hypertension.

As with other patient populations, control of hypertension should focus on both nonpharmacologic therapy (eg, diet, exercise, weight loss, treatment of obstructive sleep apnea) and pharmacologic therapy. CKD results in disturbed sodium homeostasis such that the ability of the kidney to adjust to variations in sodium and water intake becomes limited as GFR declines. The clinician should recommend institution of a diet with mildly decreased salt intake (3 g/d), and salt intake should be reduced to 2 g/d if hypertension persists or signs of CHF develop. Diuretics are nearly always needed to help control hypertension. However, volume contraction as a result of very low sodium intake or over-diuresis in the presence of impaired sodium homeostasis can result in further impairment of the GFR. In addition to diuretics, initial drug therapy should include ACE inhibitors or ARBs as recommended by national guidelines (if serum potassium permits). When an ACE inhibitor or an ARB is initiated or uptitrated, patients should have serum creatinine and potassium checked within 5–14 days. Hyperkalemia or a rise in serum creatinine > 30% from baseline mandates reduction or cessation of the drug. Second-line antihypertensive agents include calcium channel-blocking agents and β-blocking agents. Because of the difficulty in controlling hypertension in CKD, additional agents from other classes are often needed. Current guidelines suggest a blood pressure goal of 130/80 mm Hg for patients with CKD; a goal of 125/75 mm Hg is recommended for patients with proteinuria. It should be noted that treatment of blood pressure significantly below these goals is not supported by current data and may be dangerous in some populations, such as the elderly. Ongoing randomized controlled trials are looking at the benefit of systolic blood pressure goals of < 120 mm Hg versus < 140 mm Hg regarding outcomes such as ESRD and cardiac death in high-risk populations.

2. Coronary artery disease—Patients with CKD are at higher risk for death from cardiovascular disease than the general population. Traditionalmodifiable risk factors for cardiovascular disease, such as hypertension, tobacco use, and hyperlipidemia, should be aggressively treated in patients with CKD. Uremic vascular calcification involving disordered phosphorus homeostasis and other mediators may also be a cardiovascular risk factor in these patients.

Figure 22–2. Complications of chronic kidney disease (CKD) by stage and glomerular filtration rate (GFR). Complications arising from CKD tend to occur at the stages depicted, although there is considerable variability noted in clinical practice. HTN, hypertension; PTH, parathyroid hormone. (Adapted, with permission, from William Bennett, MD.)
3. Congestive heart failure—The complications of CKD result in increased cardiac workload via underlying hypertensive disease, volume overload, and anemia. Patients with CKD may also have accelerated rates of atherosclerosis, and vascular calcification resulting in vessel stiffness. All of these factors contribute to left ventricular hypertrophy and diastolic dysfunction, which are present in most patients starting dialysis. Over time, systolic dysfunction may also develop. Water and salt restriction is usually necessary. Diuretics are of value if they can affect an increased urine volume, although thiazides are ineffective by themselves when the GFR is < 20–30 mL/min/1.73 m². Loop diuretics are commonly used, potentially in combination with thiazide diuretics, and higher doses are required as renal function declines. Digoxin is excreted by the kidney, and its toxicity is exacerbated in the presence of electrolyte disturbances which are common in CKD. The proven efficacy of ACE inhibitors in congestive heart failure holds true for patients with CKD. Despite the risks of hyperkalemia and worsening renal function, ACE inhibitors and ARBs can be used for patients with a serum creatinine > 3 mg/dL with close supervision and laboratory test monitoring.

4. Pericarditis—Pericarditis may develop in uremic patients but is rare. Symptoms include chest pain and fever. Pulser paradoxus can be present; a friction rub may be auscultated, but the lack of a rub does not rule out a significant pericardial effusion. The chest radiograph can show an enlarged cardiac silhouette, and the ECG, generalized ST and T wave changes, characteristically a progression from diffuse ST elevation followed by a return to baseline and then T wave inversion. If pericardial effusion occurs, the ECG often shows nonspecific T wave changes and low QRS voltage; electrical alternans is a pathognomonic finding. Cardiac tamponade can occur; patients with tamponade have signs of poor cardiac output, with jugular venous distention and lungs clear to auscultation. Uremic pericarditis is a mandatory indication for hospitalization and initiation of hemodialysis.

B. Disorders of Mineral Metabolism

The metabolic bone disease of CKD refers to the complex disturbances of calcium and phosphorus metabolism, parathyroid hormone (PTH), active vitamin D, and possibly fibroblast growth factor-23 (FGF-23) homeostasis (see Chapter 21 and Figure 22–3). A typical pattern seen as early as CKD stage 3 is hyperphosphatemia, hypocalcemia, hypovitaminosis D, and secondary hyperparathyroidism as a result of the first three abnormalities. Traditionally, the emphasis on treating these disturbances centered around concern for the consequential bone disease and increased fracture risk noted in CKD patients. Now it is recognized that such disturbances also lead to vascular calcification and may be partly responsible for the accelerated cardiovascular disease and excess mortality seen in the CKD population. Epidemiologic studies in humans show an association between elevated phosphorus levels and increased risk of cardiovascular mortality in early CKD through ESRD. As yet, there are no intervention trials suggesting the best course of treatment in these patients; control of mineral and PTH levels per current guidelines is discussed below.

Bone disease, or renal osteodystrophy, in advanced CKD is common and there are several types of lesions. Renal osteodystrophy can only be diagnosed by bone biopsy, which is rarely done. The most common bone disease, osteitis fibrosa cystica, is a result of secondary hyperparathyroidism and the osteoclast-stimulating effects of PTH. This is a high-turnover disease with osteoclastic bone resorption and subperiosteal lesions. Metastatic calcifications, such as tumor calcinosis, can occur. Radiographically, lesions are most prominent in the phalanges and lateral ends of the clavicles. Adynamic bone disease, or low-bone turnover, is becoming more common and results from relatively low PTH levels or activity; it may result iatrogenically from suppression of PTH or via spontaneously low PTH production. Osteomalacia, or lack of bone mineralization, is another lesion associated with CKD. In the past, osteomalacia was associated with aluminum toxicity—either as a result of chronic ingestion of prescribed aluminum-containing phosphorus binders or from high levels of aluminum in untreated dialysate. Currently, osteomalacia is more likely to result from hypovitaminosis D; there is also theoretical risk of osteomalacia associated with use of bisphosphonates in advanced CKD.

All of the above entities can cause bony pain, proximal muscle weakness, and higher risk for fractures. Treatment involves correction of calcium, phosphorus, and 25-OH vitamin D levels toward normal values, along with treatment of hyperparathyroidism. Understanding the interplay between these abnormalities can help target therapy (Figure 22–3). Declining GFR leads to phosphorus retention. This results in hypocalcemia as phosphorus complexes with calcium, deposits in soft tissues, and stimulates PTH. Loss of renal mass, and low 25-OH vitamin D levels often seen in CKD patients results in low 1,25(OH) vitamin D production by the kidney. Because 1,25(OH) vitamin D is a suppressor of PTH production, hypovitaminosis D also leads to secondary hyperparathyroidism.

The first step in treatment of metabolic bone disease is control of hyperphosphatemia (defined as a serum phosphorus of ≤ 4.5 mg/dL in pre-ESRD CKD, or ≤ 5.5 mg/dL in ESRD patients). This involves dietary phosphorus
reduction initially, followed by the administration of oral phosphorus binders if targets are not achieved (see below). Dietary phosphorus restriction to 1000 mg/d can be challenging as many phosphorus sources are also rich in protein; care must be taken to avoid protein malnutrition. Oral phosphorus binders, such as calcium carbonate (650 mg/tablet) or calcium acetate (667 mg/capsule), block absorption of dietary phosphorus in the gut and are given three or four times daily at the beginning of meals. These should be titrated to a serum phosphorus of <4.6 mg/dL in stage 3–4 of CKD (GFR of 15–59 mL/min) and <4.6–5.5 mg/dL in ESRD patients. National guidelines recommend maximal elemental calcium doses of 1500 mg/d (eg, nine tablets of calcium acetate); doses should be decreased if serum calcium rises above 10 mg/dL. Phosphorus-binding agents that do not contain calcium are sevelamer and lanthanum. Sevelamer, 800 mg orally, and lanthanum carbonate, 1000 mg orally, are given at the beginning of meals. Aluminum hydroxide is a highly effective phosphorus binder but can cause osteomalacia and neurologic complications when used long-term. While it can be used in the acute setting for serum phosphorus >7 mg/dL or for short periods (eg, 3 weeks) in CKD patients, long-term use should be avoided. Once serum phosphorus levels are controlled, active vitamin D (1,25(OH) vitamin D, or calcitriol) or active vitamin D analogs are recommended to treat secondary hyperparathyroidism in stage 3–5 CKD. Serum 25-OH vitamin D levels should be measured and brought to normal (see Chapter 26) prior to considering administration of active vitamin D. Active vitamin D (calcitriol) increases serum calcium and phosphorus levels; both need to be monitored closely during calcitriol therapy, and its dose should be decreased if hypercalcemia or hyperphosphatemia occurs. Typical calcitriol dosing is 0.25 or 0.5 mcg orally daily or every other day initially. Cinacalcet is a calcimetic agent that targets the calcium-sensing receptor on the chief cells of the parathyroid gland and suppresses PTH production. Cinacalcet, 30–90 mcg orally once a day, can be used if elevated serum phosphorus or calcium levels prohibit the use of vitamin D analogs; cinacalcet can cause hypocalcemia. Optimal PTH levels in CKD are not known, but because skeletal resistance to PTH develops with uremia, relatively high levels are targeted in advanced CKD to avoid adynamic bone disease. Expert guidelines generally suggest goal PTH levels near or just above the upper limit of normal for moderate CKD, and at least twofold and up to ninefold the upper limit of normal for ESRD.

C. Hematologic Complications

1. Anemia—The anemia of CKD is primarily due to decreased erythropoietin production, which often becomes clinically significant during stage 3 CKD. Many patients are iron deficient as well due to impaired GI iron absorption. Erythropoiesis-stimulating agents (eg, recombinant erythropoietin [epoetin] and darbepoetin) are FDA-approved in CKD for a goal hemoglobin (Hgb) of 10–11 g/dL; if no other treatable causes for anemia are present. One study in patients with CKD showed no benefit of starting erythropoietin-like agents before Hgb values were <9 g/dL. The dose needed can vary; the starting dose of epoetin is 50 units/kg (3000–4000 units/dose) once or twice a week. Darbepoetin is started at 0.45 mcg/kg and can be administered every 2–4 weeks. These agents can be given intravenously (eg, to the hemodialysis patient) or subcutaneously (eg, to the predialysis or dialysis patient); subcutaneous dosing of erythropoietin is roughly 30% more effective than intravenous dosing. Erythropoiesis-stimulating agents should be titrated to a Hgb of 10–11 g/dL for optimal safety; studies show that targeting a higher Hgb increases risk of stroke and possibly other cardiovascular events. When titrating doses, Hgb levels should rise no more than 1 g/dL every 3–4 weeks. Hypertension is a complication of erythropoietin or darbepoetin therapy in about 20% of patients. The dosage may require adjustment, or antihypertensive drugs may need to be given.

Iron stores must be adequate to ensure response to erythropoiesis-stimulating agents. Patients with CKD tend to have progressively increasing level of hepcidin, a molecule that blocks GI iron absorption and mobilization of iron from body stores. Therefore, traditional measures of iron stores are measured in CKD patients but are considered abnormal at a higher reference level. In CKD, a serum ferritin <100–200 ng/mL or iron saturation <20% is suggestive of iron deficiency. Iron stores should be repleted with oral or parenteral iron prior to the initiation of erythropoietic agents. Iron therapy should be withheld if the serum ferritin is >500–800 ng/mL, even if the iron saturation is <20%. Oral therapy with ferrous sulfate, gluconate, or fumarate (the latter two tend to be better tolerated), 325 mg once to three times daily, is the initial therapy for patients who are not yet receiving dialysis. For those that do not respond due to poor GI absorption or lack of tolerance, intravenous iron may be necessary. The preliminary investigation of anemia in any CKD patient should also include assessment of thyroid function tests, serum vitamin B₁₂, and red blood cell folate stores, and fecal occult blood testing prior to initiating erythropoiesis-stimulating agent therapy.

2. Coagulopathy—The coagulopathy of CKD is mainly caused by platelet dysfunction. Platelet counts may be mildly decreased, and the bleeding time is prolonged due to abnormal adhesiveness and aggregation. Clinically, patients can have petechiae, purpura, and an increased tendency for bleeding during surgery. Treatment is required only in patients who are symptomatic. Raising the Hgb to 9–10 g/dL in anemic patients can reduce bleeding time via increased blood viscosity. Desmopressin (25 mcg intravenously every 8–12 hours for two doses) is a short-lived but effective treatment for platelet dysfunction and is often used in preparation for surgery. Conjugated estrogens, 2.5–5 mg orally for 5–7 days, may have an effect for several weeks but is very seldom used. Dialysis improves the bleeding time but does not normalize it. Cryoprecipitate (10–15 bags) is rarely used and lasts <24 hours.

D. Hyperkalemia

Potassium balance generally remains intact in CKD until stages 4–5. However, hyperkalemia may occur at earlier stages
when certain conditions are present, such as type 4 renal tubular acidosis (seen in patients with diabetes mellitus), high potassium diets, or medications that decrease renal potassium secretion (amiloride, triamterene, spironolactone, eplerenone, NSAIDs, ACE inhibitors, ARBs) or block cellular potassium uptake (β-blockers). Other causes include acidiemic states, and any type of cellular destruction causing release of intracellular contents (which are high in potassium), such as hemolysis and rhabdomyolysis.

Treatment of acute hyperkalemia is discussed in Chapter 21 (see Table 21–6). Cardiac monitoring is indicated for any ECG changes seen with hyperkalemia or a serum potassium level > 6.0–6.5 mEq/L. The ion exchange resin sodium polystyrene sulfonate exchanges sodium for potassium and results in GI potassium excretion and is often used to treat acute hyperkalemia in addition to β-agonists, insulin plus glucose, and calcium gluconate as indicated. Chronic hyperkalemia is best treated with dietary potassium restriction (2 g/d) and minimization or elimination of any medications that may impair renal potassium excretion, as noted above. Loop diuretics may also be administered for their kaliuretic effect as long as the patient is not volume-depleted.

**E. Acid–Base Disorders**

Damaged kidneys are unable to excrete the 1 mEq/kg/d of acid generated by metabolism of dietary animal proteins in the typical Western diet. The resultant metabolic acidosis is primarily due to loss of renal mass; distal tubular defects may contribute to or worsen the acidosis. Although patients with CKD are in positive hydrogen ion balance, the arterial blood pH is maintained at 7.33–7.37 and serum bicarbonate concentration rarely falls below 15 mEq/L. The excess hydrogen ions are buffered by the large calcium carbonate and calcium phosphate stores in bone. This results in leaching of calcium and phosphorus from the bone and contributes to the metabolic bone disease described above. To help mitigate damage to bone and encourage normal growth, the serum bicarbonate level should be maintained at > 21 mEq/L. The most commonly used alkali salt is sodium bicarbonate. Administration should begin with 20–30 mEq/d divided into two doses per day and titrated as needed. Citrate salts increase the absorption of dietary aluminum and should be avoided in CKD patients.

**F. Neurologic Complications**

Uremic encephalopathy, resulting from the aggregation of uremic toxins, does not occur until GFR falls below 5–10 mL/min/1.73 m². Symptoms begin with difficulty in concentrating and can progress to lethargy, confusion, and coma. Physical findings may include nystagmus, weakness, asterixis, and hyperreflexia. These symptoms and signs improve after initiation of dialysis.

Neuropathy is found in 65% of CKD stage 5 and ESRD patients but can also be seen in patients with CKD stage 4. Peripheral neuropathies manifest themselves as sensorimotor polyneuropathies (stocking-glove distribution) and isolated or multiple isolated mononeuropathies; other CKD-associated neuropathies result in erectile dysfunction and autonomic dysfunction. Patients may have restless leg syndrome, loss of deep tendon reflexes, and distal pain. The earlier initiation of dialysis may prevent peripheral neuropathies, although the response to dialysis is variable.

**G. Endocrine Disorders**

In advanced CKD, circulating insulin levels are higher because of decreased renal insulin clearance, and, in diabetics, there is risk of developing dangerous hypoglycemia if this phenomenon is not anticipated. Doses of oral hypoglycemics and insulin may need reduction. Metformin is associated with risk of lactic acidosis when estimated GFR is < 60 mL/min/1.73 m² and should be discontinued at this point.

Decreased libido and erectile dysfunction are common in advanced CKD. Men have decreased testosterone levels; women are often anovulatory. Women with serum creatinine < 1.4 mg/dL are not at increased risk for poor outcomes in pregnancy; however, those with serum creatinine > 1.4 mg/dL may experience faster progression of CKD with pregnancy. Fetal survival is not compromised, however, unless CKD is advanced. Despite a high degree of infertility in patients with ESRD, pregnancy can occur in this setting—particularly in women who are well dialyzed and well nourished. However, fetal mortality approaches 50%, and babies who survive are often premature. In female patients with ESRD, renal transplantation with a well-functioning allograft affords the best chances for a successful pregnancy.

**Treatment**

**A. Slowing Progression**

Treatment of the underlying cause of CKD is vital. Control of diabetes should be aggressive in early CKD; risk of hypoglycemia increases in advanced CKD as described above, and glycemic targets may need to be relaxed to avoid this dangerous complication. Blood pressure control is vital to slow progression of all forms of CKD; agents that block the renin-angiotensin-aldosterone system are particularly important in proteinuric disease (see section on hypertension). Several small studies suggest a possible benefit of oral alkali therapy in slowing CKD progression when acidemia is present (see above); there is also theoretic value in lowering uric acid levels in those with concomitant hyperuricemia, but clinical data are lacking at this time. Management of traditional cardiovascular risk factors should also be emphasized.

**B. Dietary Management**

Every patient with CKD should be evaluated by a renal nutritionist. Specific recommendations should be made concerning protein, salt, water, potassium, and phosphorus intake to help manage CKD progression and complications.

1. **Protein restriction**—Experimental models have shown that protein restriction slows the progression to ESRD;
however, this has not been consistently proved in clinical trials. The questionable benefits of protein restriction in slowing the rate of decline of GFR must be weighed against the risk of cachexia upon the initiation of dialysis; low serum albumin at the start of dialysis is one of the strongest predictors of mortality in this population.

2. Salt and water restriction—In advanced CKD, the kidney is unable to adapt to large changes in sodium intake. Intake > 3–4 g/d can lead to edema, hypertension, and congestive heart failure, whereas intake of < 1 g/d can lead to volume depletion and hypotension. For the nondialysis patient approaching ESRD, 2 g/d of sodium is an initial recommendation. A daily intake of 2 L of fluid maintains water balance.

3. Potassium restriction—Restriction is needed once the GFR has fallen below 10–20 mL/min/1.73 m², or earlier if the patient is hyperkalemic. Patients should receive detailed lists concerning potassium content of foods and should limit their intake to < 50–60 mEq/d (2 g); this is about half of normal intake.

4. Phosphorus restriction—The phosphorus level should be kept in the 'normal' range (<4.5 mg/dL) predialysis, and between 3.5 and 5.5 mg/dL when on dialysis, with a dietary restriction of 800–1000 mg/d. Foods rich in phosphorus such as cola beverages, eggs, dairy products, nuts, beans, and meat should be limited, although care must be taken to avoid protein malnutrition. Below a GFR of 20–30 mL/ min/1.73 m², dietary restriction is rarely sufficient to reach target levels, and phosphorus binders are usually required. The treatment of hyperphosphatemia is discussed above in the section on disorders of mineral metabolism.

C. Medication Management

Many drugs are excreted by the kidney; dosages should be adjusted for GFR. Insulin doses may need to be adjusted as noted above. Magnesium-containing medications, such as laxatives or antacids, should be avoided as should phosphorus-containing medicines, particularly cathartics. Morphine metabolites are active and can accrue in advanced CKD; this problem is not encountered with other opioid agents. Drugs with potential nephrotoxicity (NSAIDs, intravenous contrast, as well as others noted in the Acute Kidney Injury section) should be avoided.

D. Treatment of End-Stage Renal Disease

When GFR declines to 5–10 mL/min/1.73 m² (with or without overt uremic symptoms), renal replacement therapy (hemodialysis, peritoneal dialysis, or kidney transplantation) is required to sustain life. Select patients with limited life expectancy because of very advanced age or comorbid conditions may choose not to pursue dialysis therapy. Patient education is very important in understanding which mode of therapy is most suitable; timely preparation for treatment is also key. Referral to a nephrologist for consideration of ESRD treatment should take place in late stage 3 CKD, or when the GFR is declining rapidly.

1. Dialysis—Dialysis initiation should be considered when GFR is 10 mL/min/1.73 m². Recent studies suggest that the well-selected patient without overt uremic symptoms may wait to initiate dialysis until GFR is closer to 7 mL/ min/1.73 m². Other indications for dialysis, which may occur when GFR is 10–15 mL/min/1.73 m² include (1) uremic symptoms, (2) fluid overload unresponsive to diuresis, (3) refractory hyperkalemia, and (4) severe metabolic acidosis (pH < 7.20). Preparation for dialysis requires a team approach. Dietitians and social workers should be involved as well as primary care clinicians and nephrologists. The patient and family need early counseling regarding the risks and benefits of therapy. For very elderly patients, or those with multiple debilitating or life-limiting comorbidities, dialysis therapy may not meaningfully prolong life, and the option of not starting dialysis with the development of ESRD should be discussed with the patient and family. Conversely, for patients who are otherwise relatively healthy, evaluation for possible kidney transplantation should be considered prior to initiation of dialysis.

A. Hemodialysis—Hemodialysis requires a constant flow of blood along one side of a semipermeable membrane with a cleansing solution, or dialysate, along the other. Diffusion and convection allow the dialysate to remove unwanted substances from the blood while adding back needed components. Vascular access for hemodialysis can be accomplished by an arteriovenous fistula (the preferred method) or prosthetic graft; creation of dialysis access should be considered well before dialysis initiation. An indwelling catheter is used when there is no useable vascular access; because catheters confer a high risk of bloodstream infections, they should be considered a temporary measure. Native fistulas typically last longer than prosthetic grafts but require a longer time (6–8 weeks or more after surgical construction) for maturation. Infection, thrombosis, and aneurysm formation are complications seen more often in grafts than fistulas. *Staphylococcus* species are the most common cause of soft-tissue infections and bacteremia.

Dialysis at a hemodialysis center occurs three times a week. Sessions last 3–5 hours depending on patient size, type of dialyzer used, and other factors. Other hemodialysis schedules can be considered depending on available resources and patient preferences. Results from nocturnal dialysis trials have not been uniform but have shown improvements over thrice weekly dialysis for blood pressure control, mineral metabolism, and quality of life. Home hemodialysis is often performed more frequently (3–6 days per week for shorter sessions) and requires a trained helper, and large equipment. The availability of these modalities is becoming more widespread; results of trials comparing these to conventional in-center dialysis have not thus far shown significant mortality differences.

B. Peritoneal dialysis—With peritoneal dialysis, the peritoneal membrane is the "dialyzer." Dialysate is instilled into the peritoneal cavity through an indwelling catheter; water and solutes move across the capillary bed that lies between the visceral and parietal layers of the membrane.
into the dialysate during a “dwell.” After equilibration, the dialysate is drained, and fresh dialysate is instilled—this is an “exchange.”

There are three kinds of peritoneal dialysis: continuous ambulatory peritoneal dialysis (CAPD), in which the patient exchanges the dialysate four to six times a day manually; continuous cyclic peritoneal dialysis (CCPD), which utilizes a cycler machine to automatically perform exchanges at night; and nocturnal intermittent peritoneal dialysis (NIPD), where patients use a cycler machine at night without any fluid in the peritoneum during the day. As with hemodialysis, peritoneal dialysis prescriptions are guided by adequacy measurements (i.e., dialytic clearance of urea).

Peritoneal dialysis permits significant patient autonomy. Its continuous nature minimizes the symptomatic volume and electrolyte shifts observed in hemodialysis patients, and poorly dialyzable compounds (such as phosphates) are better cleared, which permits less dietary restriction. However, peritoneal dialysis removes large amounts of albumin, and nutritional status must be closely watched.

The most common complication of peritoneal dialysis is peritonitis. Rates are improving (< 0.5 episodes per patient-year). Peritonitis may present with nausea and vomiting, abdominal pain, diarrhea or constipation, and fever. The dialysate is usually cloudy; and a diagnostic peritoneal fluid cell count is > 100 white blood cells/mL of which over 50% are polymorphonuclear neutrophils. *Staphylococcus aureus* is the most common infecting organism, but streptococci and gram-negative species are also common.

2. Kidney transplantation—Up to 50% of all patients with ESRD are otherwise healthy enough to be suitable for transplantation. Older age is becoming less of a barrier, as long as reasonable life expectancy is anticipated. Two-thirds of kidney allografts come from deceased donors, with the remainder from living related or unrelated donors. There are over 90,000 patients on the active waiting list for a deceased donor transplant in the United States; the average wait is 2–6 years, depending on geographic location and recipient blood type.

The 1- and 3-year kidney graft survival rates are approximately 96% and 91%, respectively, for living donor transplants and 91% and 81%, respectively, for deceased donor transplants. Factors that determine outcome include antigenic disparity (ABO blood groups and major histocompatibility or HLA) between donor and recipient, the type of immunologic response mounted by the host, and the immunosuppressive regimen used to prevent graft rejection. Nonimmunologic factors that affect the risk of chronic rejection include age and race of recipient, donor age; length of time on dialysis; and coexisting hyperlipidemia, hypertension, or cytomegalovirus infection.

Immunosuppressive regimens to prevent allograft rejection generally include a combination of a corticosteroid, an antimetabolite (azathioprine or mycophenolate mofetil), and a calcineurin inhibitor (tacrolimus or cyclosporine) or mTor inhibitor (sirolimus). Maintenance doses are lower than doses given at the time of transplant, with the aim of preventing recurrent rejection and chronic allograft nephropathy, prolonging graft survival, and minimizing potentially serious medication side effects. Aside from medication use, the life of a transplant recipient can return to nearly normal, although these patients are at higher risk for certain cancers and infections.

3. Medical management of ESRD—As noted above, some patients are not candidates for transplantation and may not benefit from dialysis. Recent studies suggest that very elderly persons who do not die soon after dialysis initiation rapidly lose functional status in the first year of treatment. The decision to initiate dialysis in patients with limited life expectancy should be weighed against possible deleterious changes in quality of life. For patients with ESRD who elect not to undergo dialysis, death occurs within days to weeks. In general, uremia develops and patients lose consciousness prior to death. Arrhythmias can occur as a result of electrolyte imbalance. Volume overload and dyspnea can be managed by volume restriction and opioids as described in Chapter 5. Involvement of a palliative care team is essential.

Prognosis in ESRD

Compared with kidney transplant recipients and age-matched controls, mortality is higher for patients undergoing dialysis. There is likely little difference in survival for well-matched peritoneal versus hemodialysis patients.

Survival rates on dialysis depend on the underlying disease process. Five-year Kaplan-Meier survival rates vary from 36% for patients with diabetes to 53% for patients with glomerulonephritis. Overall 5-year survival is currently estimated at 42%. Patients undergoing dialysis have an average life-expectancy of 3–5 years, but survival for as long as 25 years may be achieved depending on comorbidities. The most common cause of death is cardiac disease (50%). Other causes include infection (12%), cerebrovascular disease (15%), and malignancy (6%). Diabetes, advanced age, a low serum albumin, lower socioeconomic status, and inadequate dialysis are all significant predictors of mortality; high fibroblast growth factor (FGF)-23 levels have emerged as a novel marker for mortality in ESRD.

### When to Refer

- A patient with stage 3–5 CKD should be referred to a nephrologist for management in conjunction with the primary care provider.
- A patient with other forms of CKD such as those with significant proteinuria (>1 g/d) or polycystic kidney disease should be referred to a nephrologist at earlier stages.

### When to Admit

- Admission should be considered for patients with uncompensation of problems related to CKD, such as worsening of acid-base status, electrolyte abnormalities, and volume status that cannot be appropriately treated in the outpatient setting.
- Admission is appropriate when a patient needs to start dialysis and is not stable for outpatient initiation.

RENAL ARTERY STENOSIS

ESSENTIALS OF DIAGNOSIS

- Produced by atherosclerotic occlusive disease (80–90% of patients) or fibromuscular dysplasia (10–15%).
- Hypertension.
- Acute kidney injury in patients starting ACE inhibitor therapy.

General Considerations

Atherosclerotic ischemic renal disease accounts for nearly all cases of renal artery stenosis. Fibromuscular dysplasia is a rare cause of renal artery stenosis. Approximately 5% of Americans with hypertension suffer from renal artery stenosis. It occurs most commonly in those over 45 years of age with a history of atherosclerotic disease. Other risk factors include CKD, diabetes mellitus, tobacco use, and hypertension.

Clinical Findings

A. Symptoms and Signs

Patients with atherosclerotic ischemic renal disease may have refractory hypertension, new-onset hypertension (in an older patient), pulmonary edema with poorly controlled blood pressure, and acute kidney injury upon starting an ACE inhibitor. In addition to hypertension, physical examination may reveal an audible abdominal bruit on the affected side. Fibromuscular dysplasia primarily affects young women. Unexplained hypertension in a woman younger than 40 years is reason to screen for this disorder.

B. Laboratory Findings

Laboratory values can show elevated BUN and serum creatinine levels in the setting of significant renal ischemia.

C. Imaging

Abdominal ultrasound can reveal asymmetric kidney size when one renal artery is affected out of proportion to the other.

Three prevailing methods used for screening are Doppler ultrasonography, CT angiography, and magnetic resonance angiography (MRA). Doppler ultrasonography is highly sensitive and specific (>90% with an experienced ultrasonographer) and relatively inexpensive. However, this method is extremely operator and patient dependent. Measurements of blood flow must be made at the aorta and along each third of the renal artery in order to assess the disease. This test is a poor choice for patients who are obese, unable to lie supine, or have interfering bowel gas patterns.

CT angiography consists of intravenous digital subtraction angiography with arteriography and is a noninvasive procedure. The procedure uses a spiral (helical) CT scan with intravenous contrast injection. The sensitivities from various studies range from 77% to 98%, with less varying specificities in a range of 90–94%.

MRA is an excellent but expensive way to screen for renal artery stenosis, particularly in those with atherosclerotic disease. Sensitivity is 77–100%, although one study with particular flaws showed a sensitivity of only 62%. Specificity ranges from 71% to 96%. Turbulent blood flow can cause false-positive results. The imaging agent for MRA (gadolinium) has been associated with nephrogenic systemic fibrosis, which occurs primarily in patients with a GFR of <15 mL/min/1.73 m², and rarely in patients with a GFR of 15–30 mL/min/1.73 m². It has also been seen in those with acute kidney injury and kidney transplants.

Renal angiography is the gold standard for diagnosis. CO₂ subtraction angiography can be used in place of dye when the risk of dye nephropathy exists—eg, in diabetic patients with kidney injury. Lesions are most commonly found in the proximal third or ostial region of the renal artery. The risk of atheroembolic phenomena after angiography ranges from 5% to 10%. Fibromuscular dysplasia has a characteristic "beads-on-a-string" appearance on angiography.

Treatment

Treatment of atherosclerotic ischemic renal disease is controversial. Options include medical management, angioplasty with or without stenting, and surgical bypass. A 2009 study has shown that intervention is no better than optimal medical management in typical patients in whom renal artery stenosis was diagnosed via gold-standard mechanisms. Angioplasty might reduce the number of antihypertensive medications but does not significantly change the progression of kidney dysfunction in comparison to patients medically managed. Stenting produces significantly better angioplastic results. However, blood pressure is equally improved, and serum creatinine levels are similar at
Abnormalities of glomerular function can be caused by damage to the major components of the glomerulus: the epithelium (podocytes), basement membrane, capillary endothelium, or mesangium. The damage may be caused by overwork injury, such as in CKD; by an inflammatory process, such as systemic lupus erythematosus; by a podocyte protein mutation, such as in hereditary focal and segmental glomerulosclerosis; or a deposition disease, such as diabetes or amyloidosis. A specific histologic pattern of glomerular injury results from this damage and can be seen on renal biopsy.

**Classification**

Clinically, a glomerular disease can be classified as being in one of two spectra—either in the nephritic spectrum or the nephrotic spectrum (Figure 22–4). In the “least severe” end of the nephritic spectrum, the findings of glomerular hematuria (ie, dysmorphic red blood cells) are characteristic. The nephritic syndrome, comprising glomerular hematuria, subnephrotic proteinuria (<3 g/d), edema, and elevated creatinine, falls in the mid-portion of the spectrum. The rapidly progressive glomerulonephritides are at the “most severe” and clinically urgent end of the nephritic spectrum.

The nephrotic spectrum comprises diseases that present with primarily proteinuria of at least 0.5–1 g/d and a bland urine sediment (no cells or cellular casts). The more severe end of the nephrotic spectrum comprises the nephrotic syndrome, which is characterized by the constellation of nephrotic-range proteinuria (>3 g/d), edema, and hyperlipidemia. Differentiating between a clinical presentation within the nephritic spectrum versus the nephrotic spectrum.

**Figure 22–4.** Glomerular diseases present within one of the clinical spectra shown, the exact presentation is determined by the severity of the underlying disease and the pattern of injury. Nephritic diseases are characterized by the presence of an active urine sediment with glomerular hematuria and often with proteinuria. Nephrotic spectrum diseases are proteinuric with bland urine sediments (no cells or cellular casts). All glomerular diseases may progress to a chronic, scarred state. (Adapted, with permission, from Megan Troxell, MD, PhD.)
nephrotic spectrum is important because it helps narrow the differential diagnosis of the underlying glomerular disease (Tables 22–9 and 22–10).

Glomerular diseases can also be classified according to whether they cause only renal abnormalities (primary renal disease) or whether the renal abnormalities result from a systemic disease (secondary renal disease).

Further evaluation prior to renal biopsy may include serologic testing for systemic diseases that can result in glomerular damage (Figure 22–5).
Chapter 22

CMDT 2013

Inflammatory process causing renal dysfunction. It can be acute, developing over days to weeks, with or without resolution, or may be more chronic and indolent with progressive scarring. As noted above, diseases that cause a nephritic spectrum presentation may present with glomerular hematuria with some proteinuria, with nephritic syndrome, or with rapidly progressive glomerulonephritis (Figure 22–4). The presentation depends on the severity of the underlying inflammation and the pattern of injury caused by the disease process.

Clinical Findings

A. Symptoms and Signs

If the nephritic syndrome is present, edema is first seen in regions of low tissue pressure such as the periorbital and scrotal areas. Hypertension in the nephritic syndrome is due to sodium retention resulting from acute decrease in GFR. Heavy glomerular bleeding from inflammation may result in gross hematuria (smoky or cola-colored urine).

Table 22–10. Classification and findings in glomerulonephritis: Nephrotic spectrum presentations.

ESRD, end-stage renal disease; GFR, glomerular filtration rate; HAART, highly active antiretroviral therapy; NSAIDs, nonsteroidal anti-inflammatory drugs; PLA2R, phospholipase A2 receptor; SLE, systemic lupus erythematosus; SPEP/UPEP: serum and urine protein electrophoresis.

Nephritic Spectrum Glomerular Diseases

Essentials of Diagnosis

- Glomerular hematuria (dysmorphic red blood cells), possibly red blood cell urinary casts.
- Less than nephrotic range proteinuria (0.3–3 g/d).
- Hypertension is common.
- Entity classified into one of three groups: asymptomatic glomerular hematuria, acute nephritic syndrome, or rapidly progressive glomerulonephritis.
- Edema, if present, in dependent (eg, periorbital or scrotal) areas.

General Considerations

Glomerulonephritis is a term given to those diseases that present in the nephritic spectrum and usually signifies an inflammatory process causing renal dysfunction. It can be acute, developing over days to weeks, with or without resolution, or may be more chronic and indolent with progressive scarring. As noted above, diseases that cause a nephritic spectrum presentation may present with glomerular hematuria with some proteinuria, with nephritic syndrome, or with rapidly progressive glomerulonephritis (Figure 22–4). The presentation depends on the severity of the underlying inflammation and the pattern of injury caused by the disease process.
B. Laboratory Findings

1. Serologic testing—Serologic tests, including complement levels, antinuclear antibodies, cryoglobulins, hepatitis serologies, ANCA s, anti-GBM antibodies, and antistreptolysin O (ASO) titers (Figure 22–5), are done based on the history and physical examination to narrow the differential diagnosis of the nephritic spectrum disorder.

2. Urinalysis—The urinalysis shows protein and red blood cells. On microscopy, these cells are misshapen from traversing a damaged capillary membrane—so-called dysmorphic red blood cells. Red blood cell casts are seen with heavy glomerular bleeding and tubular stasis. When quantified, proteinuria is usually subnephrotic (<3 g/d).

3. Biopsy—Renal biopsy should be considered if there are no contraindications (eg, bleeding disorders, thrombocytopenia, uncontrolled hypertension). Light microscopy delineates the pattern of injury; underlying disease process can be further categorized according to the immunofluorescence pattern and appearance on electron microscopy.

Treatment

General measures for all include aggressive treatment of hypertension and fluid overload if present. Dialysis may be needed as discussed in the acute kidney injury section. The inflammatory glomerular injury may require corticosteroids or cytotoxic agents, or both. (See specific diseases discussed below.)

When to Refer

Any patient in whom a glomerulonephritis is suspected should be referred to a nephrologist.

When to Admit

Any suspicion of acute nephritic syndrome or rapidly progressive glomerulonephritis warrants consideration of immediate hospitalization.

POSTINFECTIOUS GLOMERULONEPHRITIS

ESSENTIALS OF DIAGNOSIS

- Proteinuria.
- Glomerular hematuria.
- Symptoms 1–3 weeks after infection (often pharyngitis or impetigo).

General Considerations

Postinfectious glomerulonephritis is most often due to infection with nephritogenic group A β-hemolytic streptococci. It can occur sporadically or in clusters and during epidemics. It commonly appears after pharyngitis or impetigo with onset 1–3 weeks after infection (average 7–10 days).

Other infections have been associated with postinfectious glomerulonephritis including bacteremic states (especially with S aureus), bacterial pneumonias, deep-seated abscesses, gram-negative infections, infective endocarditis, and shunt infections. Viral, fungal, and parasitic causes of postinfectious glomerulonephritis pattern of glomerular injury include hepatitis B or C, HIV, cytomegalovirus infection, infectious mononucleosis, coccidioidomycosis, malaria, mycobacteria, syphilis, and toxoplasmosis.

Clinical Findings

A. Symptoms and Signs

Disease presentation can vary widely across the nephritic spectrum from asymptomatic glomerular hematuria (especially in epidemic cases) to nephritic syndrome with hypertension, oliguria, edema, and perhaps cola-colored urine.

B. Laboratory Findings

Serum complement levels are low; in postinfectious glomerulonephritis due to group A streptococcal infection, anti-streptolysin O (ASO) titers can be high unless the immune response has been blunted with previous antibiotic treatment. Glomerular hematuria and subnephrotic proteinuria are present; severe cases may demonstrate elevated serum creatinine and red cell casts in the urine. Renal biopsy shows a diffuse proliferative pattern of injury on light microscopy. Immunofluorescence shows IgG and C3 in a granular pattern in the mesangium and along the capillary basement membrane. Electron microscopy shows large, dense subepithelial deposits or “humps.”

Treatment

The underlying infection should be identified and treated appropriately, but otherwise, treatment for postinfectious glomerulonephritis is supportive. Antihypertensives, salt restriction, and diuretics should be used if needed. Corticosteroids have not been shown to improve outcome. Prognosis depends on the severity of the glomerular injury and age of the patient. Children are more likely to fully recover; adults are more prone to the development of severe disease (rapidly progressive glomerulonephritis with crescent formation) and CKD.

IGA NEPHROPATHY

ESSENTIALS OF DIAGNOSIS

- Proteinuria: minimal to nephrotic range.
- Glomerular hematuria: microscopic is common; macroscopic (gross) after infection.
- Positive IgA staining on renal biopsy.
**General Considerations**

IgA nephropathy (Berger disease) is a primary renal disease of IgA deposition in the glomerular mesangium. The inciting cause is unknown but is likely due to abnormal glycosylation of IgA subclass 1 molecules. IgA nephropathy can be a primary (renal-limited) disease, or it can be secondary to hepatic cirrhosis, celiac disease, and infections such as HIV and cytomegalovirus. Susceptibility to IgA nephropathy seems to be inheritable.

IgA nephropathy is the most common primary glomerular disease worldwide, particularly in Asia. It is most commonly seen in children and young adults, with males affected two to three times more commonly than females.

**Clinical Findings**

An episode of gross hematuria is the most common presenting symptom. Frequently, this is associated with an upper respiratory infection (50%), GI symptoms (10%), or a flu-like illness (15%). The urine becomes red or cola-colored 1–2 days after illness onset. In contrast to postinfectious glomerulonephritis, this feature has been called “synpharyngitic hematuria” since there is no significant latent period. IgA nephropathy can present as any of the nephritic syndromes from asymptomatic microscopic hematuria to rapidly progressive glomerulonephritis. Rarely, it can present as a nephrotic syndrome.

There are no serologic tests that aid in the diagnosis of IgA nephropathy; serum IgA subclass 1 testing may be a possibility in the future. Serum complement levels are normal. The typical pattern of injury seen on renal biopsy is a focal glomerulonephritis with mesangial proliferation; immunofluorescence demonstrates diffuse mesangial IgA and C3 deposits.

**Treatment**

The disease course of primary IgA nephropathy varies widely among patients; treatment approach needs to be tailored to risk for progression. Patients with low risk for progression (no hypertension, normal GFR, minimal proteinuria) can be monitored annually. Patients at medium to high risk (proteinuria > 0.5 g/d, decreased GFR, or hypertension, or any combination of these three conditions) should be given an initial course of conservative treatment, including ACE inhibitor orARB therapy and blood pressure control to 130/80 mm Hg. For those in this risk category who have nephrotic syndrome or a rapid decline in GFR, or those in whom proteinuria is not suppressed to < 1 g/d but have relatively preserved GFR (stage 3 CKD or less), immunosuppressive therapy should be considered. In patients with proteinuria of 1.0–3.5 g/d and GFR > 70 mL/min/1.73 m², corticosteroid therapy has proven beneficial. One such regimen (methylprednisolone, 1 g/d intravenously for 3 days during months 1, 3, and 5, plus prednisone in a dosage of 0.5 mg/kg orally every other day for 6 months) showed a 2% doubling of creatinine after 6 years in the treatment group versus a 21% doubling of creatinine in the control group. For patients with a GFR < 70 mL/min/1.73 m² and a predicted progression to ESRD in < 5 years, some experts have suggested a trial of low-dose cyclophosphamide followed by maintenance azathioprine. Kidney transplantation is an excellent option for patients with ESRD, but recurrent disease has been documented in 30% of patients 5–10 years posttransplant. Fortunately, recurrent disease rarely leads to failure of the allograft.

**Prognosis**

Approximately one-third of patients experience spontaneous clinical remission. Progression to ESRD occurs in 20–30% of patients. The remaining patients show chronic microscopic hematuria and a stable serum creatinine. The most unfavorable prognostic indicator is proteinuria > 1 g/d; other unfavorable prognostic indicators include hypertension, persistent microscopic hematuria and proteinuria, glomerulosclerosis or glomerular crescents on biopsy, and abnormal GFR on presentation.

**HENOCH-SCHÖNLEIN PURPURA**

Henoch-Schönlein purpura is a small-vessel leukocytoclastic vasculitis associated with IgA subclass 1 deposition in vessel walls. It is most common in children and is often associated with an infecting illness, such as group A streptococcus or other exposure. There is a male predominance. It classically presents with palpable purpura in the lower extremities and buttock area; arthralgias; and abdominal symptoms, such as nausea, colic, and melena. A decrease in GFR is common with a nephritic presentation. The renal lesions are considered by most experts to be identical to those found in IgA nephropathy. Most patients with microscopic hematuria and minimal proteinuria recover fully over several weeks. Progressive CKD and possibly ESRD are more likely to develop in those with the nephrotic syndrome and the presence of both nephritic and nephrotic syndrome poses the worst renal prognosis. Histologic classification of the lesions in children may also provide prognostic information. To date, although several treatment regimens of various immunosuppressive agents have been clinically tested, none have been definitively proven to alter the course of severe Henoch-Schönlein purpura nephritis. Rituximab treatment and plasma exchange have been successful for severe disease according to several case reports, but clinical trials are lacking.

Further details about Henoch-Schönlein purpura are provided in Chapter 20.

Pillebout E et al; CESAR study group. Addition of cyclophosphamide to steroids provides no benefit compared with steroids alone in treating adult patients with severe Henoch Schönlein purpura. Kidney Int. 2010 Sep;78(5):495–502. [PMID: 20505654]
PAUCI-IMMUNE GLOMERULONEPHRITIS (ANCA-Associated)

Pauci-immune necrotizing glomerulonephritis is caused by the following systemic ANCA-associated small-vessel vasculitides: granulomatosis with polyangiitis, microscopic polyangiitis, and Churg-Strauss disease (see Chapter 20). ANCA-associated glomerulonephritis can also present as a primary renal lesion without systemic involvement; this is termed "idiopathic crescentic glomerulonephritis." The precise pathogenesis of these entities is unknown; it is likely that ANCs are responsible for neutrophil activation and consequent vascular damage. Immunofluorescence of renal biopsy specimens do not reveal any evidence of immunoglobulin or complement deposition, hence the term "pauci-immune." Renal involvement classically presents as a rapidly progressive glomerulonephritis.

Clinical Findings

A. Symptoms and Signs

Symptoms of a systemic inflammatory disease, including fever, malaise, and weight loss may be present and usually precede initial presentation by several months. In addition to hematuria and proteinuria from glomerular inflammation, some patients exhibit purpura from dermal capillary involvement and mononeuritis multiplex from nerve arteriolar involvement. Ninety percent of patients with granulomatosis with polyangiitis have upper (especially sinus) or lower respiratory tract symptoms with nodular lesions that can cavitate and bleed. Hemoptysis is a concerning sign and usually warrants hospitalization.

B. Laboratory Findings

Serologically, ANCA subtype analysis is done. A c-ANCA is specific for antiproteinase-3 antibodies (PR3-ANCA), while a p-ANCA is specific for antimiteloperoxidase antibodies (MPO-ANCA). Most patients with granulomatosis with polyangiitis are c-ANCA positive; the remainder can have a p-ANCA pattern or rarely do not demonstrate ANCA serologically. Microscopic angiitis has either a p-ANCA or c-ANCA pattern about 80% of the time. As noted above, the small vessels and glomeruli lack immune deposits on immunofluorescence. Necrotizing lesions and crescents are the pattern of injury associated with this rapidly progressive glomerulonephritis.

Treatment

Treatment should be instituted early. Induction therapy of high-dose corticosteroids (methylprednisolone, 1–2 g/d intravenously for 3 days, followed by prednisone, 1 mg/kg orally for 1 month, with a slow taper over the next 6 months) and cytotoxic agents (cyclophosphamide, 0.5–1 g/m² intravenously per month or 1.5–2 mg/kg orally for 3–6 months) is followed by long-term azathioprine or mycophenolate mofetil. Plasma exchange has been shown to be beneficial in conjunction with induction therapy; however, a recent meta-analysis calls into question the strength of this benefit. Rituximab has recently been shown to be noninferior to cyclophosphamide for induction.

Prognosis

Without treatment, prognosis is extremely poor. However, with aggressive treatment, complete remission can be achieved in about 75% of patients. Prognosis depends on the extent of renal involvement before treatment is started. ANCA titers should be monitored to follow treatment efficacy; rising titers herald relapse. Patients receiving cyclophosphamide should receive prophylaxis for Pneumocystis jiroveci, such as trimethoprim-sulfamethoxazole double-strength orally 3 days per week.

ANTI-GLOMERULAR BASEMENT MEMBRANE GLOMERULONEPHRITIS & GOODPASTURE SYNDROME

Goodpasture syndrome is defined by the clinical constellation of glomerulonephritis and pulmonary hemorrhage; injury to both is mediated by antibodies to epitopes in the GBM (Figure 22–5). Up to one-third of patients with anti-GBM glomerulonephritis have no evidence of concomitant lung injury. Anti-GBM-associated glomerulonephritis accounts for 10–20% of patients with rapidly progressive acute glomerulonephritis. The incidence peaks in the second and third decades of life during which time males are predominantly affected and lung involvement is more common, and again in the sixth and seventh decades with less gender predominance. Lung involvement has been associated with pulmonary infection, tobacco use, and hydrocarbon solvent exposure; HLA-DR2 and -B7 antigens may predispose as well.

Clinical Findings

A. Symptoms and Signs

The onset of disease is preceded by an upper respiratory tract infection in 20–60% of cases; hemoptysis, dyspnea, and possible respiratory failure may ensue. Other findings are consistent with a rapidly progressive acute glomerulonephritis, although some cases may present with much milder forms of the nephritic spectrum of disease (eg, glomerular hematuria and proteinuria with minimal renal dysfunction).

B. Laboratory Findings

Laboratory evaluation can show iron deficiency anemia if pulmonary hemorrhage has been prolonged. Serum
complement levels are normal. Sputum may contain hemosiderin-laden macrophages. Chest radiographs can show shifting pulmonary infiltrates due to pulmonary hemorrhage. The diffusion capacity of carbon monoxide is markedly increased. Diagnosis is confirmed by finding circulating anti-GBM antibodies, which are positive in over 90% of patients. About 15% of patients also have elevated ANCA titers; these patients should be treated with plasma exchange as for anti-GBM disease. Renal biopsy typically shows crescent formation on light microscopy, with linear IgG staining along the GBM on immunofluorescence.

**Treatment**

The treatment of choice is a combination of plasma exchange therapy to remove circulating antibodies, and administration of immunosuppressive drugs to prevent formation of new antibodies and control the inflammatory response. Corticosteroids are typically given initially in pulse doses of methylprednisolone, 1–2 g/d for 3 days, then prednisone orally 1 mg/kg/d. Cyclophosphamide is administered intravenously at a dose of 0.5–1 g/m² per month or orally at a dosage of 2–3 mg/kg/d. Daily plasma exchange is performed for up to 2 weeks. A poorer prognosis exists in patients with oliguria and a serum creatinine > 6–7 mg/dL, or requiring dialysis upon presentation. Anti-GBM antibody titers should decrease as the clinical course improves.

### CRYOglobulin-associated GLOMERULONEPHRITIS

Essential (mixed) cryoglobulinemia is a disorder associated with cold-precipitable immunoglobulins (cryoglobulins). Glomerular disease results from the precipitation of cryoglobulins in glomerular capillaries (Figure 22–5). The cause is typically hepatitis C infection, but other infections (such as hepatitis B) or other occult or clinically apparent viral, bacterial, and fungal infections can be causative; it is also associated with some connective tissue diseases.

Patients exhibit purpuric and necrotizing skin lesions in dependent areas, arthralgias, fever, and hepatosplenomegaly. Serum complement levels are depressed. Rheumatoid factor is often elevated when cryoglobulins are present. Renal biopsy may show several different patterns of injury; there may be crescent formation, glomerular capillary thrombi, or MPGN (see below). Treatment consists of aggressively targeting the causative infection. Pulse corticosteroids, plasma exchange, and cytotoxic agents have been used when risk of exacerbating the underlying infection is resolved. Interferon-α (IFN-α) has been shown to benefit patients with hepatitis C–related cryoglobulinemia; in patients who do not respond to such treatment or for whom antiviral treatment is not indicated, there is some suggestion that rituximab may improve renal outcomes.

### IDIOPATHIC MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

MPGN in its primary form is an idiopathic renal disease that usually presents with nephritic features ranging from asymptomatic glomerular hematuria and proteinuria, to episodes of gross hematuria, to the acute nephritic syndrome. MPGN may also present with the nephrotic syndrome. Most patients are under 30 years of age, and a recent history of upper respiratory tract infection is present in nearly half. At least two major subgroups are recognized: type I and type II. Both are characterized by hypocomplementemia; in type I MPGN, the classic complement pathway is activated, leading to low or normal C3 with low C4, whereas in type II disease, the alternative complement pathway is activated and C3 is low while C4 is normal. Prognosis is worse in type II disease.

Renal biopsy in type I MPGN demonstrates a thickened GBM due to immune complex deposition and abnormal mesangial cell proliferation between the GBM and the endothelial cells. This gives a characteristic “splitting” or “tram-track” appearance to the capillary wall. Immunofluorescence shows IgG, IgM, and granular deposits of C3, C1q, and C4. Subendothelial deposits are seen on electron microscopy.

**Type II MPGN** (dense deposit disease) is less common than type I and is associated with C3 nephritic factor, a circulating IgG antibody. Light microscopy is similar to type I. Electron microscopy shows a characteristic ribbon-like deposit of homogeneous material that replaces part of the GBM.

Treatment of idiopathic MPGN is controversial. After ruling out secondary or systemic causes, treatment of children with nephrotic syndrome consists of corticosteroids at 40 mg/m² every other day for a prolonged duration. Uncontrolled studies suggest that there may be some role for other immunosuppressive regimens, including cyclophosphamide, cyclosporine, and mycophenolate mofetil. ACE inhibitors and ARBs should be used to treat hypertension and proteinuria. Adults are less likely to respond to corticosteroid treatment. In the past, 50% of patients progressed to ESRD in 10 years; this rate may now be slightly lower with the introduction of more aggressive therapy. Less favorable prognostic findings include type II MPGN, early renal insufficiency, hypertension, and persistent nephrotic syndrome. Both types of MPGN will recur after renal transplantation; however, type II recurs more commonly. Plasma exchange has been used with mixed results to treat post-transplant recurrence of MPGN.

HEPATITIS C VIRUS INFECTION

Renal disease in the setting of hepatitis C viral infection was not well-recognized until 1993. Now it accounts for approximately 8% of patients with ESRD. The three patterns of renal injury associated with hepatitis C are secondary MPGN, cryoglobulinemic glomerulonephritis, and membranous nephropathy. A type I MPGN (see section above) is the most common lesion found on kidney biopsy. These patients typically have hematuria and proteinuria, hypertension, and anemia. Occasionally, they also exhibit features of the nephrotic syndrome. Many patients have elevated serum transaminases and an elevated rheumatoid factor. Hypocomplementemia is very common, with C4 typically more reduced than C3. Cryoglobulinemic disease is discussed above. Membranous glomerulopathy is the least common of the three and presents with a typical nephrotic picture; neither cryoglobulins nor rheumatoid factor is present.

Treatment

In patients with hepatitis C virus–associated MPGN not receiving treatment for liver disease, the question arises whether to initiate therapy for kidney disease. The main indications for therapy are poor renal function, nephrotic syndrome, new or worsening hypertension, fibrosis or tubulointerstitial disease on biopsy, and progressive disease. IFN-α may result in suppression of viremia and improvement in hepatic function. Renal function rarely improves unless viral suppression occurs; however, renal function often worsens when therapy is abated. Ribavirin is relatively contraindicated in kidney disease because of the dose-related hemolysis that occurs with renal dysfunction. Despite this, some case series have shown benefit with combined IFN-α and ribavirin in closely monitored settings.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus is an autoimmune disease in which renal involvement is common. In various series, renal involvement ranges from 35% to 90% (see Chapter 20), with the higher estimates encompassing subclinical disease.

Lupus nephritis may present as any entity in the spectrum of clinical glomerular disease, although most presentations are as glomerulonephritis. Nonglomerular syndromes include tubulointerstitial nephritis and vasculitis. All patients with systemic lupus erythematosus should have routine urinalyses to monitor for the appearance of hematuria or proteinuria. If urinary abnormalities are detected, renal biopsy is often performed. The 2003 International Society of Nephrology and Renal Pathology Society (ISN/RPS) classification of renal glomerular lesions is class I, minimal mesangial nephritis; class II, mesangial proliferative nephritis; class III, focal (<50% of glomeruli affected with capillary involvement) proliferative nephritis; class IV, diffuse (>50% of glomeruli affected with capillary involvement) proliferative nephritis; class V, membranous nephropathy; and class VI, advanced sclerosis without residual disease activity. Classes III and IV, the most severe forms of lupus nephritis, are further classified as active or chronic, and global or segmental, which confers additional prognostic value.

Treatment

Individuals with class I and class II lesions require no treatment. Transformation of these types to a more active lesion may occur and is usually accompanied by an increase in lupus serologic activity and evidence of deteriorating renal function (eg, rising serum creatinine, increasing proteinuria). Repeat biopsy to confirm the transformation in these patients is recommended. Patients with extensive class III lesions and all class IV lesions should receive aggressive immunosuppressive therapy. The features signifying the poorest prognosis in patients with class III or IV lesions include elevated serum creatinine, lower complement levels, male sex, presence of antiphospholipid antibodies, nephrotic-range proteinuria, black race, and poor response to therapy. Indications for treatment of class V lesions are unclear; however, if superimposed proliferative lesions exist, aggressive therapy should be instituted.

Treatment of proliferative lupus nephritis consists of induction therapy, followed by maintenance treatment. All induction therapy includes corticosteroids (eg, methylprednisolone 1 g intravenously daily for 3 days followed by prednisone, 1 mg/kg orally daily with subsequent taper over 4–6 weeks) in combination with either cyclophosphamide or mycophenolate mofetil. Current data suggest that blacks and Hispanics respond more favorably to mycophenolate mofetil rather than cyclophosphamide; in addition, mycophenolate mofetil has a more favorable side-effect profile than does cyclophosphamide. Cyclophosphamide induction regimens vary but usually involve monthly intravenous pulse doses (500–750 mg/m²) for 4–8 months. Induction is followed by daily oral mycophenolate mofetil or azathioprine maintenance therapy. A recent trial showed that mycophenolate mofetil was superior to azathioprine maintenance and caused few adverse effects. Mycophenolate mofetil induction is typically given at 2–3 g/d, then tapered to 1–2 g/d for maintenance. Tacrolimus or cyclosporine may also be considered, but the relapse rate is high upon discontinuation of these agents. Rituximab has also been used for induction therapy, but clinical trial data are lacking. Remission rates with induction vary from 80% for partial remission to 50–60% for full remission; it may take more than 6 months to see these effects. Relapse is common and rates of disease flare are higher in those who do not experience complete remission; similarly, progression to ESRD is more common in those who relapse more frequently, or in whom no remission has been achieved.

The normalization of various laboratory tests (double-stranded DNA antibodies, serum C3, C4, CH50 levels) can be useful in monitoring treatment. Urinary protein levels and sediment activity are also helpful markers. Patients with systemic lupus erythematosus who undergo dialysis have a
favourable prospect for long-term survival; interestingly, systemic lupus symptoms may become quiescent with the development of ESRD. Patients with systemic lupus erythematosus undergoing kidney transplants have recurrent renal disease in 8% of cases.

NEPHROTIC SPECTRUM GLOMERULAR DISEASES

ESSENTIALS OF DIAGNOSIS

- Bland urine sediment (few if any cells or cellular casts).
- Full-blown nephrotic syndrome consists of the following:
  - Urine protein excretion > 3 g per 24 hours.
  - Hypoalbuminemia (albumin < 3 g/dl).
  - Peripheral edema.
  - Hyperlipidemia.
  - Oval fat bodies in the urine.

General Considerations

In adults, about one-third of patients with nephrotic syndrome have a systemic disease such as diabetes mellitus, amyloidosis, or systemic lupus erythematosus. With the current epidemic of type 2 diabetes mellitus, the proportion with diabetes is slowly increasing. The remaining have proteinuria due to primary renal disease. The most common causes are minimal change disease, focal segmental glomerulosclerosis, membranous nephropathy, and MPGN (see above). Any of these disease processes can present on the less severe end of the spectrum with a bland urinalysis and proteinuria, or with the full-blown nephrotic syndrome. Serum creatinine may or may not be abnormal at the time of presentation, depending on the severity, acuity and chronicity of the disease.

Clinical Findings

A. Symptoms and Signs

Peripheral edema is a hallmark of the nephrotic syndrome, occurring when the serum albumin concentration is < 3 g/dL (30 g/L). Edema is most likely due to sodium retention and, at albumin levels < 2 g/dL (20 g/L), arterial underfilling from low plasma oncotic pressure. Initially, this presents in the dependent areas of the body subject to gravity, such as the lower extremities; however, such edema can become generalized, including notable periorbital edema. Patients can experience dyspnea due to pulmonary edema, pleural effusions, and diaphragmatic compromise with ascites. Complaints of abdominal fullness may also be present in patients with ascites.

Patients with the nephrotic syndrome may also have an increase incidence of infection owing to loss of immunoglobulins and certain complement moieties in the urine; similarly, there can be increased risk of venous thrombosis secondary to loss of anticoagulant factors.

B. Laboratory Findings

1. Urinalysis—Proteinuria occurs as a result of effacement of podocytes (foot processes) and an alteration of the negative charge of the GBM. The screening test for proteinuria is the urinary dipstick analysis; however, this test indicates albumin only. The addition of sulfosalicylic acid to the urine sediment allows abnormal paraproteins to be detected. A spot urine protein to urine creatinine ratio gives a reasonable approximation of grams of protein excreted per day.

Microscopically, the urinary sediment has relatively few cellular elements or casts. However, if marked hyperlipidemia is present, the urine can have oval fat bodies resulting from lipid deposits in sloughed renal tubular epithelial cells. They appear as “grape clusters” under light microscopy and “Maltese crosses” under polarized light.

2. Blood chemistries—The nephrotic syndrome results in hyperalbuninemia (< 3 g/dL [30 g/L]) and hypoproteinemia (< 6 g/dL [60 g/L]). Hyperlipidemia occurs in over 50% of patients with early nephrotic syndrome, and becomes more frequent and worsens in degree as the severity of the nephritic syndrome increases. A fall in oncotic pressure triggers increased hepatic production of lipids (cholesterol and apolipoprotein B). There is also decreased clearance of very low-density lipoproteins, causing hypertriglyceridemia. Patients may also have an elevated erythrocyte sedimentation rate as a result of alterations in some plasma components such as increased levels of fibrinogen. Patients may become deficient in vitamin D, zinc, and copper from loss of binding proteins in the urine.

Laboratory testing to determine the underlying cause may include complement levels, serum and urine protein electrophoresis, antinuclear antibodies, and serologic tests for hepatitis.

3. Renal biopsy—Renal biopsy is often performed in adults with new-onset idiopathic nephrotic syndrome if a primary renal disease that may require drug therapy (eg, corticosteroids, cytotoxic agents) is suspected. Chronically and significantly elevated creatinine levels may indicate irreversible kidney disease mitigating the usefulness of kidney biopsy. In the setting of long-standing diabetes mellitus type 1 or 2, proteinuric renal disease is rarely biopsied unless atypical features (such as significant glomerular hematuria or cellular casts) are also present, or if there is other reason to suspect a second renal lesion.
Treatment

A. Protein Loss

The daily total dietary protein intake should replace the daily urinary protein losses so as to avoid negative nitrogen balance. Protein malnutrition often occurs with urinary protein losses > 10 g/d. In the past, protein restriction was suggested for patients with kidney disease. The largest human trial to date (the MDRD Study) did not show a significant benefit, but two meta-analyses in 1999 and 2001 have shown a mild renal benefit. For this reason, the KDOQI recommends protein restriction to 0.6–0.8 g/kg/d in patients with a GFR < 25 mL/min/1.73 m² prior to starting dialysis. However, great care must be taken to avoid malnutrition in these patients.

In both diabetic and nondiabetic patients, therapy that is aimed at reducing proteinuria may also reduce progression of renal disease. ACE inhibitors and ARBs lower urine protein excretion by lowering efferent arteriolar resistance, thereby reducing glomerular capillary pressure; they also have antifibrotic effects. ACE inhibitors and ARBs can be used in patients with reduced GFR as long as significant hyperkalemia (potassium > 5.2–5.5 mEq/L) does not occur and serum creatinine rises < 30%; these patients should be monitored closely to avoid acute kidney injury and hyperkalemia. The combination of an ACE inhibitor and ARB versus ARB alone for slowing the progression of diabetic nephropathy is being tested in a multicenter, prospective randomized study.

B. Edema

Dietary salt restriction is essential for managing edema; most patients also require diuretic therapy. Commonly used diuretics include thiazide and loop diuretics (both are highly protein bound). With hypoalbuminemia and decreased GFR, diuretic delivery to the kidney is reduced, and patients often require larger doses. A combination of loop and thiazide diuretics can potentiate the diuretic effect. This may be needed for patients with refractory fluid retention.

C. Hyperlipidemia

Hypercholesterolemia and hypertriglyceridemia occur as noted above. Dietary modification and exercise should be advocated; however, effective lipid-lowering usually also requires pharmacologic treatment (see Chapter 28). Statins are hepatically cleared, so dosage is not altered for CKD. Rhabdomyolysis, however, is more common in patients with CKD who take gemfibrozil in combination with statins; combining fenofibrate or niacin with a statin poses less risk of rhabdomyolysis.

D. Hypercoagulable State

Patients with serum albumin < 2 g/dL can become hypercoagulable. Nephrotic patients have urinary losses of antithrombin, protein C, and protein S and increased platelet activation. Patients are prone to renal vein thrombosis and other venous thromboemboli, particularly with membranous glomerulopathy. Anticoagulation therapy is warranted for at least 3–6 months in patients with evidence of thrombosis in any location. Patients with renal vein thrombosis or recurrent thromboemboli require indefinite anticoagulation.

When to Refer

Any patient noted to have nephrotic syndrome should be referred immediately to a nephrologist for aggressive volume and blood pressure management, assessment for renal biopsy, and treatment of the underlying disease. Proteinuria of > 1 g/d without the nephrotic syndrome also merits nephrology referral, though with less urgency.

When to Admit

Patients with edema refractory to outpatient therapy or rapidly worsening kidney function that may require inpatient interventions should be admitted.

Clinical Findings
A. Symptoms and Signs
Patients often exhibit the manifestations of full-blown nephrotic syndrome. They are more susceptible to infection, especially with gram-positive organisms, have a tendency toward thromboembolic events, develop severe hyperlipidemia, and experience protein malnutrition. Minimal change disease can rarely cause acute kidney injury due to tubular changes and interstitial edema.

B. Histologic Findings
Glomeruli show no changes on light microscopy or immunofluorescence. On electron microscopy, there is a characteristic effacement of podocyte foot processes. A subgroup of patients also shows mesangial cell proliferation; such patients have more hematuria and hypertension and poor response to standard corticosteroid treatment.

Treatment
Treatment is with prednisone, 60 mg/m²/d orally. Adults response to standard corticosteroid treatment.

General Considerations
Membranous nephropathy is the most common cause of primary nephrotic syndrome in adults, usually presenting in the fifth and sixth decades. It is an immune-mediated disease characterized by immune complex deposition in the subepithelial portion of glomerular capillary walls. The antigen in the primary form of the disease appears to be a phospholipase A₂ receptor (PLA₂R) on the podocyte in 70–80% of patients. Secondary disease is associated with underlying carcinomas; infections, such as hepatitis B, endocarditis, and syphilis; autoimmune diseases, such as systemic lupus erythematosus, mixed connective tissue disease, and thyroiditis; and certain drugs, such as penicillamine and captopril. The course of disease is variable, with about 50% of patients progressing to ESRD over 3–10 years. Poorer outcome is associated with concomitant tubulointerstitial fibrosis, male sex, elevated serum creatinine, hypertension, and heavy proteinuria (>10 g/d).

Clinical Findings
A. Symptoms and Signs
Patients with membranous nephropathy and nephrotic syndrome have a higher risk of hypercoagulable state than those with nephrosis from other etiologies; there is a particular predisposition to renal vein thrombosis in these patients. There may be symptoms or signs of an underlying infection or neoplasm (especially lung, stomach, breast, and colon cancers) in secondary membranous nephropathy.

B. Laboratory Findings
See above for laboratory findings in the nephrotic syndrome. Serum evaluation for circulating PLA₂R antibodies to assess for idiopathic membranous nephropathy may be available in the future. By light microscopy, capillary wall thickness is increased without inflammatory changes or cellular proliferation; when stained with silver methenamine, a “spike and dome” pattern may be observed owing to projections of excess GBM between the subepithelial deposits. Immunofluorescence shows IgG and C3 uniformly along capillary loops. Electron microscopy shows a discontinuous pattern of dense deposits along the subepithelial surface of the basement membrane.

Treatment
Treatment is controversial. After underlying causes are excluded, treatment depends on the risk of renal disease progression. One algorithm is based on the degree of proteinuria. In patients with proteinuria <3.5 g/d, the risk of progression is low. These individuals should be closely monitored with a low-salt diet, strict blood pressure control, and an ACE inhibitor or ARB for reduction of proteinuria. Patients with proteinuria of 3.5–8 g/d but normal renal function are at moderate risk. They should follow the above suggestions and can elect immunosuppressive regimens with corticosteroids and chlorambucil or cyclophosphamide for 6 months, although only 65% of these patients experience partial or complete remission within 3–4 years.

ESSENTIALS OF DIAGNOSIS

- Nephrotic range proteinuria.
- Associated with coagulopathy, eg, renal vein thrombosis, if nephrotic syndrome present.
- “Spike and dome” pattern on kidney biopsy from subepithelial deposits.
- Secondary causes notably include hepatitis B virus and carcinomas.
Cyclosporine is a second choice. The highest-risk patients—those with > 8 g/d of proteinuria and possible renal dysfunction—might receive corticosteroids with a cytotoxic agent as first-line immunosuppressant therapy, though the choice of cyclosporine is also reasonable. Mycophenolate mofetil and rituximab are becoming more widely accepted as possible first-line agents of treatment or for patients who relapse or do not tolerate other immunosuppressive agents. Patients with primary membranous nephropathy are excellent candidates for transplant.

**FOCAL SEGMENTAL GLOMERULOSESCLEROSIS**

This lesion can present as idiopathic disease or secondary to such conditions as heroin use, morbid obesity, chronic urinary reflux, and HIV infection. Idiopathic disease may be related to heritable abnormalities of any of several podocyte proteins. Clinically, patients with nephrotic spectrum findings may have overt nephrotic syndrome. Decreased kidney function is present in 25–50% at time of diagnosis. Patients with focal segmental glomerulosclerosis and nephrotic syndrome typically progress to ESRD in 6–8 years.

Diagnosis requires renal biopsy. Light microscopy shows sclerosis of portions (or segments) of some, but not all glomeruli (thus, focal and not diffuse disease). IgM and C3 are seen in the sclerotic lesions on immunofluorescence, although it is presumed that these immune components are simply trapped in the sclerotic glomeruli and are not participating in the pathogenesis of the disease. Electron microscopy shows fusion of epithelial foot processes as seen in minimal change disease.

Treatment for primary focal segmental glomerulosclerosis is controversial, although supportive care for nephrotic patients is indicated (diuretics for edema, ACE inhibitors or ARBs to target proteinuria and hypertension, statins or niacin for hyperlipidemia). High-dose oral prednisone (1–1.5 mg/kg/d) for 2–3 months followed by a slow taper can induce remission within 5–9 months in over half of patients. Other cytotoxic drug therapy can be considered for steroid-resistant patients, including calcineurin inhibitors and mycophenolate mofetil. For those patients with primary focal segmental glomerulosclerosis who progress to ESRD and undergo renal transplantation, relapse rate and graft loss is relatively high; plasma exchange therapy just prior to transplant and with early signs of relapse appear to be beneficial in lowering risk of these outcomes.

### AMYLOIDOSIS

Amyloidosis is caused by extracellular deposition of the fibrous protein amyloid in one or more sites in the body. The amyloid fibrils are composed of proteins that have formed characteristic β-pleated sheets. Primary renal amyloidosis (AL amyloidosis) may occur in the absence of systemic disease or associated with multiple myeloma; indeed, both are plasma cell dyscrasias, which overproduce immunoglobulin light chain (the amyloid protein). Serum and urine protein electrophoresis can be helpful in delineating the light chain present in such cases. Secondary amyloidosis (AA amyloidosis) is due to a chronic inflammatory disease, such as rheumatoid arthritis, inflammatory bowel disease, or chronic infection. In these cases, acute phase reactant serum amyloid A is synthesized in the liver and deposited in the tissues. Amyloid-affected kidneys can be enlarged as a result of this deposition disease. Pathologically, glomeruli are filled with amorphous deposits that stain positive with Congo red and show green birefringence.

Treatment options are few. Remissions can occur in secondary amyloidosis if the inciting agent is removed. Primary amyloidosis of the kidney progresses to ESRD in an average of 2–3 years. Five-year overall survival is <20%, with death occurring from ESRD and heart disease. The use of alkylating agents and corticosteroids—eg, melphalan and prednisone—can reduce proteinuria and improve renal function in a small percentage of patients. Significant reduction in free light chain burden (>90%) has been shown to correlate with improved renal outcomes. Melphalan and stem cell transplantation are associated with high toxicity (45% mortality) but induce remission in 80% of the remaining patients. Renal transplant is an option in patients with secondary amyloidosis.

**DIABETIC NEPHROPATHY**

**ESSENTIALS OF DIAGNOSIS**

- Prior evidence of diabetes mellitus, typically over 10 years.
- Albuminuria (microscopic or macroscopic) precedes decline in GFR.
- Signs of diabetic nephropathy on renal biopsy, if done.
- Other end-organ damage, such as retinopathy, is common.

**General Considerations**

Diabetic nephropathy is the most common cause of ESRD in the United States (about 4000 cases a year). Type 1 diabetes mellitus carries a 30–40% risk of nephropathy after 20 years, whereas type 2 has a 15–20% risk after 20 years. ESRD is much more likely to develop in persons with type 1 diabetes mellitus, in part due to fewer comorbidities and deaths before ESRD ensues. With the current epidemic of obesity and type 2 diabetes mellitus, rates of diabetic nephropathy are projected to continue to increase. Patients at higher risk include males, African Americans, and Native Americans.

**Clinical Findings**

The first stage of diabetic nephropathy is hyperfiltration, with an increase in GFR, followed by the development of microalbuminuria (30–300 mg/d). As the nephropathy progresses, (macro)albuminuria (> 300 mg/d, or enough to be detected on regular dipstick) is seen, and the GFR returns to normal and then goes on to decrease. Yearly screening for the development of microalbuminuria is recommended for all diabetic patients. In patients prone to nephropathy, microalbuminuria develops within 10–15 years after onset of diabetes and progresses over the next 3–7 years to overt proteinuria (> 300 mg of albuminuria per day).

The most common lesion in diabetic nephropathy is diffuse glomerulosclerosis, but nodular glomerulosclerosis (Kimmelstiel-Wilson nodules) is pathognomonic. The kidneys in these patients are usually enlarged as a result of cellular hypertrophy and proliferation.

Patients with diabetes are prone to other renal disease. These include papillary necrosis, chronic interstitial nephritis, and type 4 (hyporeninemic hypoaldosteronemic) renal tubular acidosis. Patients are more susceptible to acute kidney injury from many insults, including intravenous contrast material and concomitant use of renin-angiotensin blockers (eg, ACE inhibitors) and NSAIDs. In diabetic patients with consequent comorbidities, there is a poor prognosis once dialysis is begun.

**Treatment**

With the onset of microalbuminuria, aggressive treatment is necessary. Strict glycemic control and treatment of hypertension have been proven to slow progression of disease; current guidelines support a goal blood pressure of 130/80 mm Hg in most patients, and possibly 120/75 mm Hg in overtly proteinuric patients. In particular, ACE inhibitors and ARBs lower the rate of progression to clinical proteinuria and slow progression to ESRD by reducing intraglomerular pressure as well as by treating hypertension; they may also have antifibrotic effects. Even in the subset of patients with markedly diminished GFR, these agents seem to provide renal benefit if patients can avoid hyperkalemia and as long as GFR does not decline more than 30% with the initiation of this therapy. Some experts have advocated for combination ACE inhibitor and ARB therapy as a way to maximally target proteinuria; however, the ONTARGET trial suggested great caution in using combination therapy because of the development of hyperkalemia and worsening kidney function in the group given both telmisartan and ramipril.

**HIV-ASSOCIATED NEPHROPATHY**

HIV-associated nephropathy can present as the nephrotic syndrome in patients with HIV infection. Decline in GFR can progress rapidly. Most patients are black, possibly because of a genetic predisposition. Often, patients have low CD4 counts and have advanced HIV disease, but HIV-associated nephropathy can also be the initial presentation of disease.

Light microscopy shows focal segmental glomerulosclerosis as described above. Lesions are often of the collapsing variety, and renal biopsy specimens also exhibit severe tubulointerstitial damage.

Small, uncontrolled studies have shown that highly active antiretroviral therapy (HAART) for a prolonged course can slow progression of disease. Despite this minimal evidence, HAART has been recommended for use in these patients given the therapy’s other beneficial effects and reasonable toxicity profile. Either ACE inhibitors or ARBs can be used to control blood pressure and slow disease progression. Corticosteroid treatment has been used with variable success at a dosage of 1 mg/kg/d, along with cyclosporine.

Tubulointerstitial disease may be acute or chronic. Acute disease is most commonly associated with medications, infectious agents, and systemic rheumatologic disorders. Interstitial edema, infiltration with polymorphonuclear neutrophils, and tubular cell necrosis can be seen. (See Acute Kidney Injury, above, and Table 22–11.) Chronic disease is associated with insults from an acute factor or progressive insults without any obvious acute cause. Interstitial fibrosis and tubular atrophy are present, with a mononuclear cell predominance. The chronic disorders are described below.

### General Considerations

The primary causes of chronic tubulointerstitial disease are discussed below. Other causes include multiple myeloma and gout, which are discussed in the section on multisystem disease with variable kidney involvement.

#### A. Obstructive Uropathy

The most common cause of chronic tubulointerstitial disease is prolonged obstruction of the urinary tract. In partial obstruction, patients can exhibit polyuria (possibly due to vasopressin insensitivity and poor ability to concentrate the urine) or oliguria (due to decreased GFR). Azotemia and hypertension (due to increased renin-angiotensin production) are usually present. The major causes are prostatic disease in men; ureteral calculus in a single functioning kidney; bilateral ureteral calculi; carcinoma of the cervix, colon, or bladder; and retroperitoneal tumors or fibrosis.

Abdominal, rectal, and genitourinary examinations are helpful. Urinalysis can show hematuria, pyuria, and bacteriuria but is often benign. Abdominal ultrasound may detect mass lesions, hydroureter, and hydronephrosis. CT scanning and MRI provide more detailed information.

#### B. Vesicoureteral Reflux

Reflux nephropathy is primarily a disorder of childhood and occurs when urine passes retrograde from the bladder to the kidneys during voiding. It is the second most common cause of chronic tubulointerstitial disease. It occurs as a result of an incompetent vesicoureteral sphincter. Urine can extravasate into the interstitium; an inflammatory response develops, and fibrosis occurs. The inflammatory response is due to either bacteria or normal urinary components.

Patients are typically diagnosed as young children with a history of recurrent urinary tract infections. This entity can be detected before birth via screening fetal ultrasonography. After birth, a voiding cystourethrogram can be done. Less commonly, this entity is not diagnosed until adolescence or young adulthood when patients present with hypertension and substantial proteinuria, unusual in most tubular diseases. At this point, renal ultrasound or IVP can show renal scarring and hydronephrosis. IVP is relatively contraindicated in patients with kidney dysfunction who are at higher risk for contrast nephropathy. On renal biopsy, focal glomerulosclerosis can be seen in those with kidney damage. Although most damage occurs before age 5 years, progressive renal deterioration to ESRD continues as a result of the early insults.

#### C. Analgesics

Analgesic nephropathy is most commonly seen in patients who ingest large quantities of analgesic combinations. The drugs of concern are phenacetin, paracetamol, aspirin, and NSAIDs, with acetaminophen a possible but less certain culprit. Ingestion of at least 1 g/d for 3 years of these
Clinical Findings

A. Symptoms and Signs

Polyuria is common because tubular damage leads to inability to concentrate the urine. Volume depletion can also occur as a result of a salt-wasting defect in some individuals.

B. Laboratory Findings

Patients can become hyperkalemic both because the GFR is lower and the distal tubules become aldosterone resistant. A hyperchloremic renal tubular acidosis is characteristic from a component of type 4 or type 1 renal tubular acidosis. Less commonly, a proximal renal tubular acidosis is seen due to direct proximal tubular damage. The cause of the renal tubular acidosis is threefold: (1) reduced ammonia production, (2) inability to acidify the distal tubules, and (3) proximal tubular bicarbonate wasting. The urinalysis is nonspecific, as opposed to that seen in acute interstitial nephritis. Proteinuria is typically < 2 g/d (owing to inability of the proximal tubule to reabsorb freely filterable proteins); a few cells may be seen; and broad waxy casts are often present.

Treatment

Treatment depends first on identifying the disorder responsible for kidney dysfunction. The degree of interstitial fibrosis that has developed can help predict recovery of renal function. Once there is evidence for loss of parenchyma (small shrunken kidneys or interstitial fibrosis on biopsy), little can prevent the progression toward ESRD. Treatment is then directed at medical management. Tubular dysfunction may require potassium and phosphorus restriction and sodium, calcium, or bicarbonate supplements.

If hydronephrosis is present, relief of obstruction should be accomplished promptly. Prolonged obstruction leads to further tubular damage—particularly in the distal nephron—which may be irreversible despite relief of obstruction. Neither surgical correction of reflux nor medical therapy with antibiotics can prevent deterioration toward ESRD once renal scarring has occurred.

Patients in whom lead nephropathy is suspected should continue chelation therapy with EDTA if there is no evidence of irreversible renal damage (eg, renal scarring or small kidneys). Continued exposure should be avoided.

Treatment of analgesic nephropathy requires withdrawal of all analgesics. Stabilization or improvement of renal function may occur if significant interstitial fibrosis is not present. Hydration during exposure to analgesics may also have some beneficial effects.

When to Refer

- Patients with stage 3–5 CKD should be referred to a nephrologist when tubulointerstitial diseases are suspected. Other select cases of stage 1–2 CKD should also be referred.
- Patients with urologic abnormalities should be referred to a urologist.

tubular elements. One or more simple cysts are found in 50% of individuals over the age of 50 years. They are rarely symptomatic and have little clinical significance. In contrast, generalized cystic diseases are associated with cysts scattered throughout the cortex and medulla of both kidneys and can progress to ESRD (Table 22–12).

### SIMPLE OR SOLITARY CYSTS

Simple cysts account for 65–70% of all renal masses. They are generally found at the outer cortex and contain fluid that is consistent with an ultrafiltrate of plasma. Most are found incidentally on ultrasonographic examination. Simple cysts are typically asymptomatic but can become infected.

The main concern with simple cysts is to differentiate them from malignancy, abscess, or polycystic kidney disease. Renal cystic disease can develop in dialysis patients. These cysts have a potential for progression to malignancy. Ultrasound and CT scanning are the recommended procedures for evaluating these masses. Simple cysts must meet three sonographic criteria to be considered benign: (1) echo free, (2) sharply demarcated mass with smooth walls, and (3) an enhanced back wall (indicating good transmission through the cyst). Complex cysts can have thick walls, calcifications, solid components, and mixed echogenicity. On CT scan, the simple cyst should have a smooth thin wall that is sharply demarcated. It should not enhance with contrast media. A renal cell carcinoma will enhance but typically is of lower density than the rest of the parenchyma. Arteriography can also be used to evaluate a mass preoperatively. A renal cell carcinoma is hypervascular in 80%, hypovascular in 15%, and avascular in 5% of cases.

If a cyst meets the criteria for being benign, periodic reevaluation is the standard of care. If the lesion is not consistent with a simple cyst, follow-up with a urologic consultant and possible surgical exploration is recommended.

**AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE**

**ESSENTIALS OF DIAGNOSIS**

- Multiple cysts in bilateral kidneys; total number depends on age.
- Large, palpable kidneys on examination.
- Combination of hypertension and abdominal mass suggestive of disease.
- Family history is compelling but not necessary.
- Chromosomal abnormalities present in some patients.

**General Considerations**

This disorder is among the most common hereditary diseases in the United States, affecting 500,000 individuals, or 1 in 800 live births. Fifty percent of patients will have ESRD by age 60 years. The disease has variable penetrance but accounts for 10% of dialysis patients in the United States. At least two genes account for this disorder: *ADPKD1* on the short arm of chromosome 16 (85–90% of patients) and *ADPKD2* on chromosome 4 (10–15%). Patients with the *PKD2* mutation have slower progression of disease and longer life expectancy than those with *PKD1*. Other sporadic cases without these mutations have also been recognized.

**Clinical Findings**

Abdominal or flank pain and microscopic or gross hematuria are present in most patients. A history of urinary tract
infections and nephrolithiasis is common. A family history is positive in 75% of cases, and > 50% of patients have hypertension (see below) that may antedate the clinical manifestations of the disease. Patients have large kidneys that may be palpable on abdominal examination. The combination of hypertension and an abdominal mass should suggest the disease. Forty to 50 percent have concurrent hepatic cysts. Pancreatic and splenic cysts occur also. Hemoglobin and hematocrit tend to be maintained as a result of erythropoietin production by the cysts. The urinalysis may show hematuria and mild proteinuria. In patients with \textit{PKD1}, ultrasonography confirms the diagnosis—two or more cysts in patients under age 30 years (sensitivity of 88.5%), two or more cysts in each kidney in patients age 30–59 years (sensitivity of 100%), and four or more cysts in each kidney in patients age 60 years or older are diagnostic for autosomal dominant polycystic kidney disease. If sonographic results are unclear, CT scan is recommended and highly sensitive.

\section*{Complications & Treatment}

\subsection*{A. Pain}
Abdominal or flank pain is caused by infection, bleeding into cysts, and nephrolithiasis. Bed rest and analgesics are recommended. Cyst decompression can help with chronic pain.

\subsection*{B. Hematuria}
Gross hematuria is most commonly due to rupture of a cyst into the renal pelvis, but it can also be caused by a kidney stone or urinary tract infection. Hematuria typically resolves within 7 days with bed rest and hydration. Recurrent bleeding should suggest the possibility of underlying renal cell carcinoma, particularly in men over age 50 years.

\subsection*{C. Renal Infection}
An infected renal cyst should be suspected in patients who have flank pain, fever, and leukocytosis. Blood cultures may be positive, and urinalysis may be normal because the cyst does not communicate directly with the urinary tract. CT scans can be helpful because an infected cyst may have an increased wall thickness. Bacterial cyst infections are difficult to treat. Antibiotics with cystic penetration should be used, eg, fluoroquinolones or trimethoprim-sulfamethoxazole and chloramphenicol. Treatment may require 2 weeks of parenteral therapy followed by long-term oral therapy.

\subsection*{D. Nephrolithiasis}
Up to 20% of patients have kidney stones, primarily calcium oxalate. Hydration (2–3 L/d) is recommended.

\subsection*{E. Hypertension}
Fifty percent of patients have hypertension at time of presentation, and it will develop in most patients during the course of the disease. Cyst-induced ischemia appears to cause activation of the renin–angiotensin system, and cyst decompression can lower blood pressure temporarily. Hypertension should be treated aggressively, as this may prolong the time to ESRD. (Diuretics should be used cautiously since the effect on renal cyst formation is unknown.)

\subsection*{F. Cerebral Aneurysms}
About 10–15% of these patients have arterial aneurysms in the circle of Willis. Screening arteriography is not recommended unless the patient has a family history of aneurysms or is undergoing elective surgery with a high risk of developing moderate to severe hypertension.

\subsection*{G. Other Complications}
Vascular problems include mitral valve prolapse in up to 25% of patients, aortic aneurysms, and aortic valve abnormalities. Colonic diverticula are more common in patients with polycystic kidneys.

\section*{Prognosis}
Significant research is ongoing regarding therapy. Vasopressin receptor antagonists have been successful in animal models but have not yet been shown to be helpful in slowing down progression of disease in humans. These agents lower renal epithelial cell intracellular cyclic AMP (cAMP) levels, and in vitro evidence suggests that intracellular cAMP plays a significant role in cystogenesis in polycystic kidney disease. Other agents, octreotide and sirolimus, have shown a decreased rate of cyst growth but no decrease in the rate of decline in kidney function. Avoidance of caffeine may prevent cyst formation due to effects on G-coupled proteins. Treatment of hypertension and a low-protein diet may slow the progression of disease, although this is not well proven.

\section*{MEDULLARY SPONGE KIDNEY}
This disease is a relatively common and benign disorder that is present at birth and not usually diagnosed until the fourth or fifth decade. It is caused by autosomal dominant mutations in the \textit{MCKD1} or \textit{MCKD2} genes on chromosomes 1 and 16, respectively. Kidneys have a marked irregular enlargement of the medullary and interpapillary collecting ducts. This is associated with medullary cysts that are diffuse, giving a “Swiss cheese” appearance in these regions.

\section*{Clinical Findings}
Medullary sponge kidney presents with gross or microscopic hematuria, recurrent urinary tract infections, or nephrolithiasis. Common abnormalities are a decreased urinary concentrating ability and nephrocalcinosis; less common is incomplete type I distal renal tubular acidosis. The diagnosis can be made by CT, which shows cystic dilatation of the
Multiple myeloma is a malignancy of plasma cells (see Chapter 13). Renal involvement occurs in about 25% of all patients. “Myeloma kidney” is the presence of light chain immunoglobulins (Bence Jones protein) in the urine causing renal toxicity. Bence Jones protein causes direct renal tubular toxicity and results in tubular obstruction by precipitating in the tubules. The earliest tubular damage results in Fanconi syndrome (a type II proximal renal tubular acidosis). The proteinuria seen with multiple myeloma is primarily due to light chains that are not detected on urine dipstick, which mainly detects albumin. Hypercalcemia and hyperuricemia are frequently seen. Glomerular amyloidosis can develop in patients with multiple myeloma; in these patients, dipstick protein determinations are positive due to glomerular epithelial cell foot process effacement and albumin “spilling” into Bowman capsule with resultant albuminuria. Other conditions resulting in renal dysfunction include plasma cell infiltration of the renal parenchyma and a hyperviscosity syndrome compromising renal blood flow. Therapy for acute kidney injury attributed to multiple myeloma includes correction of hypercalcemia, volume repletion, and chemotherapy for the underlying malignancy. Plasmapheresis had been considered appropriate to decrease the burden of existing monoclonal proteins while awaiting chemotherapeutic regimens to take effect. However, in the largest randomized prospective trial to date, plasmapheresis did not provide any renal benefit to these patients. Pheresis therapy still remains controversial.

Other diseases with variable involvement described elsewhere in this chapter include systemic lupus erythematosus, diabetes mellitus, and the vasculitides such as granulomatosis with polyangiitis and Goodpasture disease.

## SICKLE CELL DISEASE

Renal dysfunction associated with sickle cell disease is most commonly due to sickling of red blood cells in the renal medulla because of low oxygen tension and hypertonicity. Congestion and stasis lead to hemorrhage, interstitial inflammation, and papillary infarcts. Clinically, hematuria is common. Damage to renal capillaries also leads to diminished concentrating ability. Isothienuria (urine osmolality equal to that of serum) is routine, and patients can easily become dehydrated. Papillary necrosis occurs as well. These abnormalities are commonly encountered in sickle cell trait. Sickle cell glomerulopathy is less common but will inexorably progress to ESRD. Its primary clinical manifestation is proteinuria. Optimal treatment requires adequate hydration and control of the sickle cell disease.

## TUBERCULOSIS

The classic renal manifestation of tuberculosis is the presence of microscopic pyuria with a sterile urine culture—or “sterile pyuria.” More often, other bacteria are also present. Microscopic hematuria is often present with pyuria. Urine cultures are the gold standard for diagnosis. Three to six first morning midstream specimens should be performed to improve sensitivity. Papillary necrosis and cavitation of the renal parenchyma occur less frequently, as do ureteral strictures and calcifications. Adequate drug therapy can result in resolution of renal involvement.

## GOUT & THE KIDNEY

The kidney is the primary organ for excretion of uric acid. Patients with proximal tubular dysfunction have decreased excretion of uric acid and are more prone to gouty attacks. Depending on the pH and uric acid concentration, deposition can occur in the tubules, the interstitium, or the uretrary tract. The more alkaline pH of the interstitium causes urate salt deposition, whereas the acidic environment of the tubules and urinary tract causes uric acid crystal deposition at high concentrations.

Three disorders are commonly seen: (1) uric acid nephrolithiasis, (2) acute uric acid nephropathy, and (3) chronic urate nephropathy. Kidney dysfunction with uric acid nephrolithiasis stems from obstructive nephropathy. Acute uric acid nephropathy presents similarly to acute tubulointerstitial nephritis with direct toxicity.

---

936 CMDT 2013 CHAPTER 22
Kidney disease

from uric acid crystals. Chronic urate nephropathy is caused by deposition of urate crystals in the alkaline medium of the interstitium; this can lead to fibrosis and atrophy. Epidemiologically, hyperuricemia and gout have been associated with worsening cardiovascular outcomes.

Treatment between gouty attacks involves avoidance of food and drugs causing hyperuricemia, aggressive hydration, and pharmacotherapy aimed at reducing serum uric acid levels. These disorders are seen in both “overproducers” and “underexcretors” of uric acid. The latter situation may seem counterintuitive; however, these patients have hyperacidic urine, which explains the deposition of relatively insoluble uric acid crystals. For those with uric acid nephrolithiasis, fluid intake should exceed 3 L/d, and use of a urinary alkalinizing agent can be considered.

Nephrogenic systemic fibrosis is a multisystem disorder seen only in patients with CKD (primarily with a GFR < 15 mL/min/1.73 m², but rarely with a GFR of 15–29 mL/min/1.73 m²), acute kidney injury, and after kidney transplantation. Histopathologically, there is an increase in dermal spindle cells positive for CD34 and procollagen I. Collagen bundles with mucin and elastic fibers are also noted.

Nephrogenic systemic fibrosis was first recognized in hemodialysis patients in 1997 and has been strongly linked to use of contrast agents containing gadolinium. Incidence is projected to be 1–4% in the highest risk (ESRD) population that has received gadolinium, and lower in patients with less severe kidney dysfunction. The FDA has issued a warning regarding avoidance of exposure to this agent for patients with GFR < 30 mL/min/1.73 m².

Clinical Findings

Nephrogenic systemic fibrosis affects several organ systems, including the skin, muscles, lungs, and cardiovascular system. The most common manifestation is a debilitating fibrosing skin disorder that can range from skin-colored to erythematous papules, which coalesce to brawny patches. The skin can be thick and woody in areas and is painful out-of-proportion to findings on examination.

Treatment

Several case reports and series have described benefit for patients after treatment with corticosteroids, photopheresis, plasmapheresis, and sodium thiosulfate. The true effectiveness of these interventions is still unclear. Alternative or no imaging agents should be used for patients requiring MR with contrast at risk for nephrogenic systemic fibrosis.

HEMATURIA

ESSENTIALS OF DIAGNOSIS

- Both gross and microscopic hematuria require evaluation.
- The upper urinary tract should be imaged, and cystoscopy should be performed if there is hematuria in the absence of infection.

General Considerations

An upper tract source (kidneys and ureters) can be identified in 10% of patients with gross or microscopic hematuria. For upper tract sources, stone disease accounts for 40%, medical kidney disease (medullary sponge kidney, glomerulonephritis, papillary necrosis) for 20%, renal cell carcinoma for 10%, and urothelial cell carcinoma of the ureter or renal pelvis for 5%. Drug ingestion and associated medical problems may provide diagnostic clues. Analgesic use (papillary necrosis), cyclophosphamide (chemical cystitis), antibiotics (interstitial nephritis), diabetes mellitus, sickle cell trait or disease (papillary necrosis), a history of stone disease, or malignancy should all be investigated. The lower tract source of gross hematuria (in the absence of infection) is most commonly from urothelial cell carcinoma of the bladder. Microscopic hematuria in the male is most commonly from benign prostatic hyperplasia. The presence of hematuria in patients receiving anticoagulation therapy cannot be ascribed to the anticoagulation; a complete evaluation is warranted consisting of upper tract imaging, cystoscopy, and urine cytology (see Chapter 39 for Bladder Cancer, Cancers of the Ureter and Renal Pelvis, Renal Cell Carcinoma, and Kidney and Testis Tumors).

Clinical Findings

A. Symptoms and Signs

If gross hematuria occurs, a description of the timing (initial, terminal, total) may provide a clue to the localization of disease. Associated symptoms (ie, renal colic, irritative voiding symptoms, constitutional symptoms) should be investigated. Physical examination should emphasize signs of systemic disease (fever, rash, lymphadenopathy, abdominal or pelvic masses) as well as signs of medical kidney disease (hypertension, volume overload). Urologic evaluation may demonstrate an enlarged prostate, flank mass, or urethral disease.

B. Laboratory Findings

Initial laboratory investigations include a urinalysis and urine culture. Proteinuria and casts suggest renal origin. Irritative voiding symptoms, bacteriuria, and a positive urine culture in the female suggest urinary tract infection, but follow-up urinalysis is important after treatment to ensure resolution of the hematuria.

Further evaluation may include urinary cytology to assist in the diagnosis of bladder neoplasm.

C. Imaging

Upper tract imaging (usually abdominal and pelvic CT scanning without and with contrast) may identify neoplasms of the kidney or ureter as well as benign conditions such as urolithiasis, obstructive uropathy, papillary necrosis, medullary sponge kidney, or polycystic kidney disease. CT urography and MRI have replaced intravenous urography when imaging the upper tracts for sources of hematuria. The role of ultrasonographic evaluation of the urinary tract for hematuria is unclear. Although it may provide adequate information for the kidney, its sensitivity in detecting ureteral disease is lower. In addition, its higher degree of operator dependence may further confound the issue.

D. Cystoscopy

Cystoscopy can be used to assess for bladder or urethral neoplasm, benign prostatic enlargement, and radiation or chemical cystitis. For gross hematuria, cystoscopy is ideally performed while the patient is actively bleeding to allow better localization (ie, lateralize to one side of the upper tracts, bladder, or urethra).
Follow-up

In patients with negative evaluations, repeat evaluations may be warranted to avoid a missed malignancy; however, the ideal frequency of such evaluations is not defined. Urinary cytology can be repeated in 3–6 months, and cystoscopy and upper tract imaging after a year.

When to Refer

In the absence of infection, hematuria (either gross or microscopic) requires evaluation.

---

---

Genitourinary Tract Infections

1. Acute Cystitis

ESSENTIALS OF DIAGNOSIS

- Irritative voiding symptoms.
- Patient usually afebrile.
- Positive urine culture; blood cultures may also be positive.

General Considerations

Acute cystitis is an infection of the bladder most commonly due to the coliform bacteria (especially *Escherichia coli*) and occasionally gram-positive bacteria (enterococci). The route of infection is typically ascending from the urethra. Viral cystitis due to adenovirus is sometimes seen in children but is rare in adults. Cystitis in men is rare and implies a pathologic process such as infected stones, prostatitis, or chronic urinary retention requiring further investigation.

Clinical Findings

A. Symptoms and Signs

Irritative voiding symptoms (frequency, urgency, dysuria) and suprapubic discomfort are common. Women may experience gross hematuria, and symptoms may often appear following sexual intercourse. Physical examination may elicit suprapubic tenderness, but examination is often unremarkable. Systemic toxicity is absent.

B. Laboratory Findings

Uranalysis shows pyuria and bacteriuria and varying degrees of hematuria. The degree of pyuria and bacteriuria does not necessarily correlate with the severity of symptoms. Urine culture is positive for the offending organism, but colony counts exceeding $10^5$/mL are not essential for the diagnosis.

C. Imaging

Because uncomplicated cystitis is rare in men, elucidation of the underlying problem with appropriate investigations, such as abdominal ultrasonography or cystoscopy (or both), is warranted. Follow-up imaging using CT scanning is warranted if pyelonephritis, recurrent infections, or anatomic abnormalities are suspected.

Differential Diagnosis

In women, infectious processes such as vulvovaginitis and pelvic inflammatory disease can usually be distinguished by pelvic examination and uranalisis. In men, urethritis and prostatitis may be distinguished by physical examination (urethral discharge or prostatic tenderness).

Noninfectious causes of cystitis-like symptoms include pelvic irradiation, chemotherapy (cyclophosphamide), bladder carcinoma, interstitial cystitis, voiding dysfunction disorders, and psychosomatic disorders.

Prevention

Women who have more than three episodes of cystitis per year are considered candidates for prophylactic antibiotic therapy to prevent recurrence after treatment of urinary tract infection. Prior to institution of therapy, a thorough urologic evaluation is warranted to exclude any anatomic abnormality (eg, stones, reflux, fistula). The three most commonly used oral agents for prophylaxis are trimethoprim-sulfamethoxazole (40 mg/200 mg), nitrofurantoin (100 mg), and cephalexin (250 mg). Single dosing at bedtime or at the time of intercourse is the recommended schedule.

The risk of acquiring a catheter-associated urinary tract infection in hospitalized patients can be minimized by using indwelling catheters only when necessary, implementing systems to ensure removal of catheters when no longer needed, using antimicrobial catheters in high-risk patients, using external collection devices in select men, identifying significant postvoid residuals by ultrasound, maintaining proper insertion techniques, and utilizing alternatives such as intermittent catheterization. The cost of treating a catheter-associated urinary tract infection acquired by a hospitalized patient is one of the complications that is not reimbursed by the Centers for Medicare & Medicaid Services.
Treatment

Uncomplicated cystitis in women can be treated with short-term antimicrobial therapy, which consists of single-dose therapy or 1–3 days of therapy. Fluoroquinolones and nitrofurantoin are the drugs of choice for uncomplicated cystitis (Table 23–1). Trimethoprim-sulfamethoxazole can be ineffective because of the emergence of resistant organisms. In men, uncomplicated urinary tract infection is rare, and thus, the duration of antibiotic therapy depends on the underlying etiology. Hot sitz baths or urinary analgesics (phenazopyridine, 200 mg orally three times daily) may provide symptomatic relief.

Prognosis

Infections typically respond rapidly to therapy, and failure to respond suggests resistance to the selected drug or anatomic abnormalities requiring further investigation.

When to Refer

- Suspicion or radiographic evidence of anatomic abnormality.
- Evidence of urolithiasis.
- Recurrent cystitis due to bacterial persistence.

Table 23–1. Empiric therapy for urinary tract infections.

1Average wholesale price, (AWP, for AB-rated generic when available) for quantity listed. Source: Red Book Online, 2012, Thomson Reuters (Healthcare) Inc. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

2Increasing resistance noted (up to 20%).

2. Acute Pyelonephritis

**ESSENTIALS OF DIAGNOSIS**
- Fever.
- Flank pain.
- Irritative voiding symptoms.
- Positive urine culture.

**General Considerations**
Acute pyelonephritis is an infectious inflammatory disease involving the kidney parenchyma and renal pelvis. Gram-negative bacteria are the most common causative agents including *E. coli*, *Proteus*, *Klebsiella*, *Enterobacter*, and *Pseudomonas*. Gram-positive bacteria are less commonly seen but include *Enterococcus faecalis* and *Staphylococcus aureus*. The infection usually ascends from the lower urinary tract—with the exception of *S. aureus*, which usually is spread by a hematogenous route.

**Clinical Findings**
**A. Symptoms and Signs**
Symptoms include fever, flank pain, shaking chills, and irritative voiding symptoms (urgency, frequency, dysuria). Associated nausea and vomiting, and diarrhea are common. Signs include fever and tachycardia. Costovertebral angle tenderness is usually pronounced.

**B. Laboratory Findings**
Complete blood count shows leukocytosis and a left shift. Urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. White cell casts may be seen. Urine culture demonstrates heavy growth of the offending agent, and blood culture may also be positive.

**C. Imaging**
In complicated pyelonephritis, renal ultrasound may show hydronephrosis from a stone or other source of obstruction.

**Differential Diagnosis**
Acute intra-abdominal disease such as appendicitis, cholecystitis, pancreatitis, or diverticulitis must be distinguished from pyelonephritis. A normal urinalysis is usually seen in gastrointestinal disorders; however, on occasion, inflammation from adjacent bowel (appendicitis or diverticulitis) may result in hematuria or sterile pyuria. Abnormal liver function tests or elevated amylase levels may assist in the differentiation. Lower lobe pneumonia is distinguishable by the abnormal chest radiograph.

In males, the main differential diagnosis for acute pyelonephritis includes acute epididymitis, acute prostatitis, and acute cystitis. Physical examination and the location of the pain should permit this distinction.

**Complications**
Sepsis with shock can occur with acute pyelonephritis. In diabetic patients, emphysematous pyelonephritis resulting from gas-producing organisms may be life threatening if not adequately treated. Healthy adults usually recover complete kidney function, yet if coexistent kidney disease is present, scarring or chronic pyelonephritis may result. Inadequate therapy could result in abscess formation.

**Treatment**
Urine and blood cultures are obtained to identify the causative agent and to determine antimicrobial sensitivity. In the inpatient setting, intravenous ampicillin and an aminoglycoside are initiated prior to obtaining sensitivity results (Table 23–1). In the outpatient setting, quinolones may be initiated (Table 23–1). Antibiotics are adjusted according to sensitivities. Fevers may persist for up to 72 hours; failure to respond warrants imaging (CT or ultrasound) to exclude complicating factors that may require intervention. Catheter drainage may be necessary in the face of urinary retention and nephrostomy drainage if there is ureteral obstruction. In inpatients, intravenous antibiotics are continued for 24 hours after the fever resolves, and oral antibiotics are then given to complete a 14-day course of therapy. Follow-up urine cultures are mandatory following the completion of treatment.

**Prognosis**
With prompt diagnosis and appropriate treatment, acute pyelonephritis carries a good prognosis. Complicating factors, underlying kidney disease, and increasing patient age may lead to a less favorable outcome.

**When to Refer**
- Evidence of complicating factors (urolithiasis, obstruction).
- Absence of clinical improvement in 48 hours.

**When to Admit**
- Severe infections or complicating factors, evidence of sepsis or need for parenteral antibiotics.
- Need for radiographic imaging or drainage of urinary tract obstruction.

3. Acute Bacterial Prostatitis

ESSENTIALS OF DIAGNOSIS

- Fever.
- Irritative voiding symptoms.
- Perineal or suprapubic pain; exquisite tenderness common on rectal examination.
- Positive urine culture.

General Considerations

Acute bacterial prostatitis is usually caused by gram-negative rods, especially *E. coli* and *Pseudomonas* species and less commonly by gram-positive organisms (e.g., enterococci). The most likely routes of infection include ascent up the urethra and reflux of infected urine into the prostatic ducts. Lymphatic and hematogenous routes are probably rare.

Clinical Findings

A. Symptoms and Signs

Perineal, sacral, or suprapubic pain, fever, and irritative voiding complaints are common. Varying degrees of obstructive symptoms may occur as the acutely inflamed prostate swells, which may lead to urinary retention. High fevers and a warm and often excruciatingly tender prostate are detected on examination. Care should be taken to perform a gentle rectal examination, since vigorous manipulations may result in septicemia. Prostatic massage is contraindicated.

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. Urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. Urine cultures will demonstrate the offending pathogen (Table 23–2).

Differential Diagnosis

Acute pyelonephritis or acute epididymitis should be distinguishable by the location of pain as well as by physical examination. Acute diverticulitis is occasionally confused with acute prostatitis; however, the history and urinalysis should permit clear distinction. Urinary retention from benign or malignant prostatic enlargement is distinguishable by initial or follow-up rectal examination.

Treatment

Hospitalization may be required, and parenteral antibiotics (ampicillin and aminoglycoside) should be initiated until organism sensitivities are available (Table 23–1). After the patient is afebrile for 24–48 hours, oral antibiotics (e.g., quinolones) are used to complete 4–6 weeks of therapy. If urinary retention develops, urethral catheterization or instrumentation is contraindicated, and a percutaneous suprapubic tube is required. Follow-up urine culture and examination of prostatic secretions should be performed after the completion of therapy to ensure eradication.

Prognosis

With effective treatment, chronic bacterial prostatitis is rare.

When to Refer

- Evidence of urinary retention.
- Evidence of chronic prostatitis.

When to Admit

- Signs of sepsis.
- Need for surgical drainage of bladder or prostatic abscess.

4. Chronic Bacterial Prostatitis

ESSENTIALS OF DIAGNOSIS

- Irritative voiding symptoms.
- Perineal or suprapubic discomfort, often dull and poorly localized.
- Positive expressed prostatic secretions and culture.

| Table 23–2. Clinical characteristics of prostatitis and prostatodynia syndromes. |
|-----------------|-----------------|-----------------|-----------------|-----------------|
| Findings        | Acute Bacterial Prostatitis | Chronic Bacterial Prostatitis | Nonbacterial Prostatitis | Prostatodynia |
| Fever           | +                            | –                            | –                            | –                |
| Urinalysis      | +                            | –                            | –                            | –                |
| Expressed prostate secretions | Contraindicated | +                            | +                            | –                |
| Bacterial culture | +                            | +                            | –                            | –                |
General Considerations

Although chronic bacterial prostatitis may evolve from acute bacterial prostatitis, many men have no history of acute infection. Gram-negative rods are the most common etiologic agents, but only one gram-positive organism (Enterococcus) is associated with chronic infection. Routes of infection are the same as discussed for acute infection.

Clinical Findings

A. Symptoms and Signs

Clinical manifestations are variable. Some patients are asymptomatic, but most have varying degrees of irritative voiding symptoms. Low back and perineal pain are not uncommon. Many patients report a history of urinary tract infections. Physical examination is often unremarkable, although the prostate may feel normal, boggy, or indurated.

B. Laboratory Findings

Urinalysis is normal unless a secondary cystitis is present.Expressed prostatic secretions demonstrate increased numbers of leukocytes (>10 per high-power field), especially lipid-laden macrophages. However, this finding is consistent with inflammation and is not diagnostic of bacterial prostatitis (Table 23–2). Leukocyte and bacterial counts from expressed prostatic secretions do not correlate with severity of symptoms. Culture of the secretions or the post-prostatic massage urine specimen is necessary to make the diagnosis.

C. Imaging

Imaging tests are not necessary, although pelvic radiographs or transrectal ultrasound may demonstrate prostatic calculi.

Differential Diagnosis

Chronic urethritis may mimic chronic prostatitis, though cultures of the fractionated urine may localize the source of infection to the initial specimen, which would come from the urethra. Cystitis may be secondary to prostatitis, but urine samples after prostatic massage may localize the infection to the prostate. Anal disease may share some of the symptoms of prostatitis, but physical examination should permit a distinction between the two.

Treatment

Few antimicrobial agents attain therapeutic intraprostatic levels in the absence of acute inflammation. Trimethoprim does diffuse into the prostate, and trimethoprim-sulfamethoxazole is associated with the best cure rates (Table 23–1). However, increasing resistance up to 20% has been noted. Other effective agents include carbenicillin, erythromycin, cephalxin, and the quinolones. The optimal duration of therapy remains controversial, ranging from 6 to 12 weeks. Symptomatic relief may be provided by anti-inflammatory agents (indomethacin, ibuprofen) and hot sitz baths.

Prognosis

Chronic bacterial prostatitis is difficult to cure, but its symptoms and tendency to cause recurrent urinary tract infections can be controlled by suppressive antibiotic therapy.

When to Refer

- Persistent symptoms.
- Consideration of enrollment in clinical trials.

5. Nonbacterial Prostatitis

General Considerations

Nonbacterial prostatitis is the most common of the prostatitis syndromes, and its cause is unknown. Speculation implicates chlamydiae, mycoplasmas, ureaplasmas, and viruses, but no substantial proof exists. In some cases, nonbacterial prostatitis may represent a noninfectious inflammatory or autoimmune disorder. Because the cause of nonbacterial prostatitis remains unknown, the diagnosis is usually one of exclusion.

Clinical Findings

A. Symptoms and Signs

The clinical presentation is identical to that of chronic bacterial prostatitis; however, no history of urinary tract infections is present. The National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI) (http://www2.niddk.nih.gov/NR/rdonlyres/93B6388F-B429-4603-9C3C-6765BDEB49A1/0/NIHCPSIEnglish.pdf) has been validated to quantify symptoms of chronic nonbacterial prostatitis or chronic pelvic pain syndrome.

B. Laboratory Findings

Increased numbers of leukocytes are seen on expressed prostatic secretions, but all cultures are negative. Culture of the secretions or the post-prostatic massage urine specimen is necessary to make the diagnosis.

C. Imaging

Imaging tests are not necessary, although pelvic radiographs or transrectal ultrasound may demonstrate prostatic calculi.

Differential Diagnosis

Chronic urethritis may mimic chronic prostatitis, though cultures of the fractionated urine may localize the source of infection to the initial specimen, which would come from the urethra. Cystitis may be secondary to prostatitis, but urine samples after prostatic massage may localize the infection to the prostate. Anal disease may share some of the symptoms of prostatitis, but physical examination should permit a distinction between the two.

Treatment

Few antimicrobial agents attain therapeutic intraprostatic levels in the absence of acute inflammation. Trimethoprim does diffuse into the prostate, and trimethoprim-sulfamethoxazole is associated with the best cure rates (Table 23–1). However, increasing resistance up to 20% has been noted. Other effective agents include carbenicillin, erythromycin, cephalxin, and the quinolones. The optimal duration of therapy remains controversial, ranging from 6 to 12 weeks. Symptomatic relief may be provided by anti-inflammatory agents (indomethacin, ibuprofen) and hot sitz baths.
Treatment

Because of the uncertainty regarding the etiology of nonbacterial prostatitis, a trial of antimicrobial therapy directed against *Ureaplasma*, *Mycoplasma*, or *Chlamydia* is warranted. Erythromycin (250 mg orally four times daily) can be initiated for 14 days yet should be continued for 3–6 weeks only if a favorable clinical response ensues. Some symptomatic relief may be obtained with nonsteroidal anti-inflammatory agents or sitz baths. Dietary restrictions are not necessary unless the patient relates a history of symptom exacerbation by certain substances such as alcohol, caffeine, and perhaps certain foods.

Prognosis

Annoying, recurrent symptoms are common, but serious sequelae have not been identified.

6. Prostatodynia

Prostatodynia is a noninflammatory disorder that affects young and middle-aged men and has variable causes, including voiding dysfunction and pelvic floor musculature dysfunction. The term “prostatodynia” is a misnomer, as the prostate is actually normal.

Clinical Findings

A. Symptoms and Signs

Symptoms are the same as those seen with chronic prostatitis, yet there is no history of urinary tract infection. Additional symptoms may include hesitancy and interruption of flow. Patients may relate a lifelong history of voiding difficulty. Physical examination is unremarkable, but increased anal sphincter tone and periprostatic tenderness may be observed.

B. Laboratory Findings

Urinalysis is normal.Expressed prostatic secretions show normal numbers of leukocytes (Table 23–2). Urodynamic testing may show signs of dysfunctional voiding (detrusor contraction without urethral relaxation, high urethral pressures, spasms of the urinary sphincter) and is indicated in patients failing empiric trials of α-blockers or anticholinergics.

Differential Diagnosis

Normal urinalysis will distinguish it from acute infectious processes. Examination of expressed prostatic secretions will distinguish this entity from prostatitis syndromes (Table 23–2).

Treatment

Bladder neck and urethral spasms can be treated by α-blocking agents (terazosin, 1–10 mg orally once a day, or doxazosin, 1–8 mg orally once a day). Pelvic floor muscle dysfunction may respond to diazepam and biofeedback techniques. Sitz baths may contribute to symptomatic relief.

Prognosis

Prognosis is variable depending on the specific cause.

7. Acute Epididymitis

Fever.

Irritative voiding symptoms.

Painful enlargement of epididymis.

General Considerations

Most cases of acute epididymitis are infectious and can be divided into one of two categories that have different age distributions and etiologic agents. Sexually transmitted forms typically occur in men under age 40 years, are associated with urethritis, and result from *Chlamydia trachomatis* or *Neisseria gonorrhoeae*. Non-sexually transmitted forms typically occur in older men, are associated with urinary tract infections and prostatitis, and are caused by gram-negative rods. The route of infection is probably via the urethra to the ejaculatory duct and then down the vas deferens to the epididymis. Amiodarone has been associated with self-limited epididymitis, which is a dose-dependent phenomenon.

Clinical Findings

A. Symptoms and Signs

Symptoms may follow acute physical strain (heavy lifting), trauma, or sexual activity. Associated symptoms of urethritis (pain at the tip of the penis and urethral discharge) or cystitis (irritative voiding symptoms) may occur. Pain develops in the scrotum and may radiate along the spermatic cord or to the flank. Fever and scrotal swelling are usually apparent. Early in the course, the epididymis may be distinguishable from the testis; however, later the two...
may appear as one enlarged, tender mass. The prostate may be tender on rectal examination.

**B. Laboratory Findings**

Complete blood count shows leukocytosis and a left shift. In the sexually transmitted variety, Gram staining of a smear of urethral discharge may be diagnostic of gram-negative intracellular diplococci (*N gonorrhoeae*). White cells without visible organisms on urethral smear represent non-gonococcal urethritis, and *C trachomatis* is the most likely pathogen. In the non-sexually transmitted variety, urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. Urine cultures will demonstrate the offending pathogen.

**C. Imaging**

Scrotal ultrasound may aid in the diagnosis if examination is difficult because of the presence of a large hydrocele or because questions exist regarding the diagnosis.

**Differential Diagnosis**

Tumors generally cause painless enlargement of the testis. Urinalysis is negative, and examination reveals a normal epididymis. Scrotal ultrasound is helpful to define the pathology. Testicular torsion usually occurs in prepubertal males but is occasionally seen in young adults. Acute onset of symptoms and a negative urinalysis favor testicular torsion or torsion of one of the testicular or epididymal appendages. Prehn sign (elevation of the scrotum above the pubic symphysis improves pain from epididymitis) may be helpful but is not reliable.

**Treatment**

Bed rest with scrotal elevation is important in the acute phase. Treatment is directed toward the identified pathogen (Table 23–1). The sexually transmitted variety is treated with 10–21 days of antibiotics, and the sexual partner must be treated as well. Non-sexually transmitted forms are treated for 21–28 days with appropriate antibiotics, at which time evaluation of the urinary tract is warranted to identify underlying disease.

**Prognosis**

Prompt treatment usually results in a favorable outcome. Delayed or inadequate treatment may result in epididymo-orchitis, decreased fertility, or abscess formation.

**When to Refer**

- Persistent symptoms and infection despite antibiotic therapy.
- Signs of sepsis or abscess formation.

---

may or may not be present. Biopsy should be performed to exclude other causes such as carcinoma, eosinophilic cystitis, and tuberculous cystitis. The presence of submucosal mast cells is not needed to make the diagnosis of interstitial cystitis.

**Differential Diagnosis**

Exposures to radiation or cyclophosphamide are obtained by the history. Bacterial cystitis, genitai herpes, or vaginitis can be excluded by urinalysis, culture, and physical examination. A urethral diverticulum may be suspected if palpation of the urethra demonstrates an indurated mass that results in the expression of pus from the urethral meatus. Urethral carcinoma presents as a firm mass on palpation.

**Treatment**

There is no cure for interstitial cystitis, but most patients achieve symptomatic relief from one of several approaches, including hydrodistention, which is usually done as part of the diagnostic evaluation. Approximately 20–30% of patients notice symptomatic improvement following this maneuver. Also of importance is the measurement of bladder capacity during hydrodistention, since patients with very small bladder capacities (< 200 mL) are unlikely to respond to medical therapy.

Ami triptyline (10–75 mg/d orally) is often used as first-line medical therapy in patients with interstitial cystitis. Both central and peripheral mechanisms may contribute to its activity. Nifedipine (30–60 mg/d orally) and other calcium channel blockers have also demonstrated some activity in patients with interstitial cystitis. Pentosan polysulfate sodium (Elmiron) is an oral synthetic sulfated polysaccharide that helps restore integrity to the epithelium of the bladder in a subset of patients and has been evaluated in a placebo-controlled trial. Other options include intravesical instillation of dimethyl sulfoxide (DMSO) and heparin. Intravesical bacillus Calmette-Guérin (BCG) is not beneficial.

Further treatment modalities include transcutaneous electric nerve stimulation (TENS) and acupuncture. Surgical therapy for interstitial cystitis should be considered only as a last resort and may require cystourethrectomy with urinary diversion.

**When to Refer**

Persistent and bothersome symptoms in the absence of identifiable cause.

Marinkovic SP et al. The management of interstitial cystitis or painful bladder syndrome in women. BMJ. 2009 Jul 31;339:b2707. [PMID: 19648180]

**URINARY STONE DISEASE**

**ESSENTIALS OF DIAGNOSIS**

- Severe flank pain.
- Nausea and vomiting.
- Identification on noncontrast CT or ultrasonography.

**General Considerations**

Urinary stone disease is exceeded in frequency as a urinary tract disorder only by infections and prostatic disease and is estimated to afflict 240,000–720,000 Americans per year. Men are more frequently affected by urolithiasis than women, with a ratio of 2.5:1. Initial presentation predominates in the third and fourth decades. The ratio of men to women approaches parity in the sixth and seventh decades.

Urinary calculi are polycrystalline aggregates composed of varying amounts of crystallloid and a small amount of organic matrix. Stone formation requires saturated urine that is dependent on pH, ionic strength, solute concentration, and complexation. There are five major types of urinary stones: calcium oxalate, calcium phosphate, struvite (magnesium ammonium phosphate), uric acid, and cystine. The most common types are composed of calcium, and for that reason most urinary stones (85%) are radiopaque (as seen on plain abdominal radiographs). Uric acid stones can be radiolucent yet frequently are composed of a combination of uric acid and calcium oxalate and thus are frequently radiopaque. Cystine stones frequently have a smooth-edged ground-glass appearance.

Geographic factors contribute to the development of stones. Areas of high humidity and elevated temperatures appear to be contributing factors, and the incidence of symptomatic ureteral stones is greatest during hot summer months. Persons in sedentary occupations have a higher incidence of stones than manual laborers. Increasing evidence is revealing that urinary stone disease may be a precursor to subsequent cardiovascular disease.

High protein and high salt intake may be important factors in the development of urinary stones while carbohydrates and fats have not been proven to have an impact on urinary stone disease.

Genetic factors may contribute to urinary stone formation. Cystinuria is an autosomal recessive disorder. Homozygous individuals have markedly increased excretion of cystine and frequently have numerous recurrent episodes of urinary stones despite attempts to optimize medical treatment. Distal renal tubular acidosis may be
transmitted as a hereditary trait, and urolithiasis occurs in up to 75% of patients affected with this disorder.

Clinical Findings

A. Symptoms and Signs

Obstructing urinary stones usually present with acute and severe colic. Pain usually occurs suddenly and may awaken patients from sleep. It is localized to the flank, is usually severe, and may be associated with nausea and vomiting. Patients are constantly moving trying to find a comfortable position—in sharp contrast to those with an acute abdomen. The pain may occur episodically and may radiate anteriorly over the abdomen. As the stone progresses down the ureter, the pain may be referred into the ipsilateral testis or labium. If the stone becomes lodged at the ureterovesicular junction, patients will complain of marked urinary urgency and frequency and in men, pain may radiate to the tip of the penis. After the stone passes into the bladder, there typically is minimal pain with passage through the urethra. Stone size does not correlate with the severity of the symptoms.

B. Laboratory Findings

Urinalysis usually reveals microscopic or gross hematuria (~90%). However, the absence of microhematuria does not exclude urinary stones. Infection must be excluded, because the combination of infection and urinary tract obstruction requires prompt intervention as described below. Urinary pH is a valuable clue to the cause of the possible stone. Normal urine pH is 5.8–5.9. There is a normal postprandial urinary alkaline tide. Numerous dipstick measurements are valuable in the complete workup of a patient in whom urinary stones are suspected. Persistent urinary pH below 5.5 is suggestive of uric acid or cystine stones, both relatively radiolucent as seen on plain abdominal radiographs. In contrast, a persistent urinary pH > 7.2 is suggestive of a struvite infection stone, which is radiopaque on plain radiographs. Patients with calcium-based stones typically have a urinary pH between 5.5 and 6.8.

C. Metabolic Evaluation

Patients should strain their urine through cheesecloth or a urine strainer. Stone analysis should be performed on recovered stones. Controversy exists in deciding which patients need a thorough metabolic evaluation for stone disease. Patients with uncomplicated first-time stones should probably undergo blood screening for abnormalities of serum calcium, electrolytes, and uric acid as a baseline. More extensive evaluation is required in patients who have recurrent stones or those with a family history of nephrolithiasis. Patients are encouraged to change their diet to reduce sodium intake, reduce their animal protein intake during individual meals, and to ingest adequate fluid intake to achieve a voided volume of 1.5–2.0 L of urine. After these dietary changes have been initiated, a 24-hour urine collection should be obtained to ascertain urinary volume, pH, calcium, uric acid, oxalate, phosphate, sodium, and citrate excretion. Serum parathyroid hormone (PTH) and calcium can be obtained if the 24-hour urine collection reveals hypercalciuria. Table 23–3 demonstrates the diagnostic criteria for the hypercalciuric states. (See discussion below.)

D. Imaging

A plain abdominal radiograph (KUB, kidney-ureter-bladder) and renal ultrasound examination will diagnose most stones. More than 60% of patients with acute renal colic will have with a stone in the distal 4 cm of the ureter; attention should be directed to that region when examining plain radiographs and abdominal ultrasonographic studies. Spiral CT is frequently the first-line tool in evaluating flank pain. Repeated CT scans should be avoided due to the substantial radiation exposure to these patients who have recurrent stones at a young age. CT scans should be obtained in the prone position to help differentiate distal...

| Table 23–3. Diagnostic criteria of different types of hypercalciuria. |

| After calcium load | ↑               | ↑                | ↑               | ↑              | ↑                |

PTH, parathyroid hormone; ↑, elevated; ↓, low; N, normal.
ureterovesicular stones from those that have already passed into the urinary bladder. Stone density can be estimated with Hounsfield units (HU) on CT scans to help determine stone type. Stones with low HU (< 450) are typically composed of uric acid, while those with high HU (> 1200) are typically composed of calcium oxalate monohydrate. All stones whether radiopaque or radiolucent on plain abdominal radiographs will be visible on noncontrast CT except the rare calculi due to the protease inhibitor indinavir.

Medical Treatment & Prevention

To reduce the recurrence rate of urinary stones, one must attempt to achieve a stone-free status. Small stone fragments may serve as a nidus for future stone development. Selected patients must be thoroughly evaluated to reduce stone recurrence rates. Patients who have formed uric acid stones may have recurrences within months if appropriate therapy is not initiated. If no medical treatment is provided after surgical stone removal, stones will generally recur in 50% of patients within 5 years. Of greatest importance in reducing stone recurrence is an increased fluid intake. Absolute volumes are not established, but increasing fluid intake to ensure a voided volume of 1.5–2.0 L/d is recommended (average voided volume is 1.6 L/d). Patients are encouraged to ingest fluids during meals, 2 hours after each meal (when the body is most dehydrated), and prior to going to sleep in the evening—enough to awaken the patient to void—and to ingest additional fluids during the night. Increasing fluids only during daylight hours may not dilute a supersaturated urine overnight and thus initiate a new stone.

A. Diet

Sodium intake should be restricted to keep urinary sodium levels < 150 mEq/d. Increased sodium intake will increase sodium and calcium excretion, increase monosodium urates (that can act as a nidus for stone growth), increase the relative saturation of calcium phosphate, and decrease urinary citrate excretion. All of these factors encourage stone growth. Animal protein intake should be spread out through the day and not consumed during any individual meal and is best limited to 1 g/kg/d. An increased protein load during an individual meal can also increase calcium, oxalate, and uric acid excretion and decrease urinary citrate excretion.

Bran can significantly decrease urinary calcium excretion by increasing bowel transit time and mechanically binding to calcium. Excess intake of oxalate and purines can increase the incidence of stones in predisposed individuals. Dietary calcium or calcium supplements should not be routinely decreased. In fact, decreased calcium consumption has been found to increase stone recurrence. Only type II absorptive hypercalciuric patients (see below) benefit from a low calcium diet.

B. Calcium Nephrolithiasis

1. Hypercalciuric—Hypercalciuric calcium nephrolithiasis (>250 mg/24 h; >4 mg/kg/24 h) can be caused by absorptive, resorptive, and renal disorders.

Absorptive hypercalciuria is secondary to increased absorption of calcium at the level of the small bowel, predominantly in the jejunum, and can be further subdivided into types I, II, and III. Type I absorptive hypercalciuria is independent of calcium intake. There is increased urinary calcium on a regular or even a calcium-restricted diet. Treatment is centered on decreasing bowel absorption of calcium. Cellulose phosphate, a chelating agent, is an effective form of therapy. An average dose is 10–15 g in three divided doses. It binds to the calcium and impedes small bowel absorption due to its increased bulk. Cellulose phosphate does not change the intestinal transport mechanism. It should be given with meals so it will be available to bind to the dietary calcium. Taking this chelating agent prior to bedtime is ineffective. Postmenopausal women should be treated with caution. It is interesting, however, that there is no enhanced decline in bone density after long-term use. Inappropriate use may result in a negative calcium balance and a secondary parathyroid stimulation. Long-term use without follow-up metabolic surveillance may result in hypomagnesuria and secondary hyperoxaluria and recurrent calculi. Routine follow-up every 6–8 months will help encourage medical compliance and permit adjustments in medical therapy based on repeat metabolic studies.

Thiazide therapy is more commonly used and is an alternative to cellulose phosphate in the treatment of type I absorptive hypercalciuria. Thiazides decrease renal calcium excretion but have no impact on intestinal absorption. This therapy results in increased bone density of approximately 1% per year. Thiazides have limited long-term utility (<5 years) since they may lose their hypocalciuric effect with continued therapy.

Type II absorptive hypercalciuria is diet dependent and fortunately rare. Decreasing calcium intake by 50% (approximately 400 mg/d) will decrease the hypercalciuria to normal values (150–200 mg/24 h). There is no specific medical therapy.

Type III absorptive hypercalciuria is secondary to a renal phosphate leak. This results in increased vitamin D synthesis and secondarily increased small bowel absorption of calcium. This can be readily reversed by orthophosphates (250 mg orally three to four times per day), presently available without need for a prescription. Orthophosphates do not change intestinal absorption but rather inhibit vitamin D synthesis.

Resorptive hypercalciuria is secondary to hyperparathyroidism. Hypercalcemia, hypophosphatemia, hypercalciuria, and an elevated serum PTH value are found. Appropriate surgical resection of the parathyroid adenoma cures the disease and recurrent urinary stones are decreased by >90%. Medical management is invariably a failure.

Renal hypercalciuria occurs when the renal tubules are unable to efficiently reabsorb filtered calcium, and hypercalciuria results. Spilling calcium in the urine results in secondary hyperparathyroidism. Serum calcium typically is normal. Thiazides are effective long-term therapy in patients with this disorder.

2. Hyperuricosuric—Hyperuricosuric calcium nephrolithiasis is secondary to dietary purine excess or endogenous uric acid metabolic defects. Most cases (85%) can be
treated with purine dietary restrictions; those that are not reversed with dietary modification are successfully treated with allopurinol. In contrast to uric acid nephrolithiasis, patients with hyperuricosuric calcium stones typically maintain a urinary pH > 5.5. Monosodium urates absorb and adsorb inhibitors and promote heterogeneous nucleation. Hyperuricosuric calcium nephrolithiasis is initiated with epitaxy, or heterogeneous nucleation. In such situations, similar crystal structures (ie, uric acid and calcium oxalate) can grow together with the aid of a protein matrix infrastructure.

3. Hyperoxaluric—Hyperoxaluric calcium nephrolithiasis (> 40 mg oxalate/24h urine) is usually due to primary intestinal disorders. Patients usually have a history of chronic diarrhea frequently associated with inflammatory bowel disease. In these situations, increased bowel fat or bile (or both) combine with intraluminal calcium to form a soap-like product. Calcium is therefore unavailable to bind to oxalate, which is then freely and rapidly absorbed. A small increase in oxalate absorption will significantly increase stone formation. If the diarrhea or steatorrhea cannot be effectively curtailed, oral calcium should be taken with meals; the calcium can be obtained by either ingesting milk products or taking calcium carbonate supplements (250–500 mg). Excess ascorbic acid (> 2 g/d) will substantially increase urinary oxalate levels. Rare enzymatic liver defects can lead to primary hyperoxaluria that is routinely fatal without a combined liver and kidney transplantation.

4. Hypocitraturic—Hypocitraturic calcium nephrolithiasis may be secondary to chronic diarrhea, type I (distal) renal tubular acidosis, chronic hydrochlorothiazide treatment, or in any other condition that results in a metabolic acidosis. The metabolic acidosis will encourage citrate transport into the proximal tubular cells and be consumed by the citric acid cycle in their mitochondria and result in hypocitraturia (< 450 mg/24h). Hypocitraturia is frequently associated with most forms of calcium stone formation. Urinary citrate binds to calcium in solution, thereby decreasing available calcium for precipitation and subsequent stone formation. Potassium citrate supplements are usually effective treatment in these situations. Urinary citrate is decreased in acidosis and is increased during alkalosis. The potassium will supplement the frequently associated hypokalemic states, and citrate will help correct the acidosis. A typical dose is 20 mEq three times a day (available in 10-mEq waxed tablets or in solution), or 30 mEq of crystal formulations twice a day. Alternatively, oral lemonade has been shown to increase urinary citrate by about 150 mg/24h.

C. Uric Acid Calculi
The average normal urinary pH is 5.8–5.9. Urinary pH is consistently < 5.5 in persons who form uric acid stones. The pK of uric acid is 5.75, at which point half of the uric acid is ionized as a urate salt and is soluble, while the other half is insoluble. Increasing the urinary pH above 6.2 dramatically increases uric acid solubility and can effectively dissolve large calculi at a rate of 1 cm per month as seen on plain abdominal radiographs, and effectively prevents future uric acid stone formation. Urinary alkalization is the key to stone dissolution and prophylaxis. Potassium citrate is the most frequently used medication to increase urinary pH. It can be given in liquid preparation, as crystals that need to be taken with fluids, or as tablets (10 mEq), two by mouth three or four times daily. Patients with uric acid calculi should be given nitrazine pH paper with which to monitor the effectiveness of their urinary alkalization; the goal is a urinary pH > 6.2 and < 6.5 (to avoid calcium phosphate precipitation). Other contributing factors include hyperuricemia, myeloproliferative disorders, malignancy with increased uric acid production, abrupt and dramatic weight loss, and uricosuric medications. If hyperuricemia is present, allopurinol (300 mg/d orally) may be given. Although pure uric acid stones are relatively radiolucent, most have some calcium components and can be visualized on plain abdominal radiographs. Renal ultrasonography is a helpful adjunct for appropriate diagnosis and long-term management.

D. Struvite Calculi
Struvite stones are synonymous with magnesium-ammonium-phosphate or infection stones. They are most commonly seen in women with recurrent urinary tract infections recalcitrant to appropriate antibiotics. They rarely present as ureteral stones with colic without prior upper tract endourologic intervention. Frequently, a struvite stone is discovered as a large staghorn configured calculus forming a cast of the renal collecting system. Struvite stones are radiodense. Urinary pH is high, routinely above 7.2. These stones are formed secondary to urease-producing organisms, including Proteus, Pseudomonas, Providencia and, less commonly, Klebsiella, Staphylococcus, and Mycoplasma. An E coli urinary tract infection is not consistent with an infectious reservoir originating from a struvite calculus. These frequently large stones are relatively soft and amenable to percutaneous nephrolithotomy. Appropriate perioperative antibiotics are required. They can recur rapidly, and efforts should be taken to render the patient stone-free. Postoperative irrigation through nephrostomy tubes can eliminate small fragments. Acetohydroxamic acid is an effective urease inhibitor, but it is poorly tolerated by most patients because of its gastrointestinal toxicity.

E. Cystine Calculi
Cystine stones are a result of abnormal excretion of cystine, ornithine, lysine, and arginine. Cystine is the only amino acid that becomes insoluble in urine. These stones are particularly difficult to manage medically. Prevention is centered around marked increased fluid intake during the day and evening to achieve a urinary volume of 3–4 L/d, urinary alkalinization with a urinary pH > 7.0 (monitored with Nitrazine pH paper), and disulfide inhibitors such as tiopronin (α-mercaptopropionylglycine) or penicillamine. There are no known inhibitors of cystine calculi.
**Surgical Treatment**

Forced intravenous fluids will not push stones down the ureter. Effective peristalsis directing a bolus of urine down the ureter requires opposing ureteral walls to approach each other and touch, which large dilated systems cannot do. In fact, forced diuresis is counterproductive and will exacerbate the pain; a euvolemic state should be achieved. Associated fever may represent infection, a medical emergency requiring prompt drainage by a ureteral catheter or a percutaneous nephrostomy tube. Antibiotics alone are inadequate unless the obstruction is drained.

**A. Ureteral Stones**

Impediment to urine flow by ureteral stones usually occurs at two sites: at the ureteropelvic junction and at the ureterovesicular junction as the ureter enters the bladder. Prediction of spontaneous stone passage is difficult. Stones < 5–6 mm in diameter as seen on a plain abdominal radiograph usually pass spontaneously. Medical expulsive therapy with α-blockers (such as tamsulosin, 0.4 mg orally once daily) in combination with a nonsteroidal anti-inflammatory agent (such as ibuprofen 600 mg orally three times per day with a full stomach), with or without a short course of a low-dose oral corticosteroid dramatically increases the rate of spontaneous stone passage. Active medical expulsive therapy with appropriate pain medications is appropriate for the first few weeks. If stone passage fails, with or without medical expulsive therapy, or the patient has intolerable pain or persistent nausea or vomiting, therapeutic intervention is indicated. Distal ureteral stones are best managed with ureteroscopic stone extraction or in situ extracorporeal shock wave lithotripsy (SWL). Ureteroscopic stone extraction involves placement of a small endoscope through the urethra and into the ureter. Under direct vision, basket extraction or stone laser fragmentation followed by extraction is performed. Complications during endoscopic retrieval increase as the duration of attempted medical expulsive therapy increases beyond 6 weeks. Indications for earlier intervention include severe pain unresponsive to medications, fever, persistent nausea and vomiting requiring intravenous hydration, social requirements requiring return to work, or anticipated travel. Most upper tract stones that enter the bladder can exit the urethra with minimal discomfort.

In situ SWL, an alternative, utilizes an external energy source that is focused on the stone. This focused energy is additive, resulting in minimal tissue insult except at the focus where the stone is positioned with the aid of fluoroscopy or ultrasonography. This can be performed under anesthesia as an outpatient procedure and has a high stone fragmentation rate. Most stone fragments will pass uneventfully within 2 weeks, but those that have not passed within 6 weeks are unlikely to pass without intervention. Women of childbearing age are best not treated with SWL for a stone in the lower ureter because the impact on the ovary is unknown.

Proximal and midureteral stones—those above the inferior margin of the sacroiliac joint—can be treated with SWL or ureteroscopy. SWL is delivered directly to the stone (in situ) without the need to push the stone back into the renal pelvis. To help ensure adequate drainage after SWL, a double J ureteral stent may be placed, but it does not ensure passage of stone fragments. Occasionally, stone fragments will obstruct the ureter after SWL. Conservative management will usually result in spontaneous resolution with eventual passage of the stone fragments. If this is unsuccessful, adequate proximal drainage through a percutaneous nephrostomy tube will facilitate passage. In rare instances, ureteral nephrostomy tube will facilitate passage.

**B. Renal Calculi**

Patients with renal calculi presenting without pain, urinary tract infections, or obstruction need not be treated. They should be monitored with serial abdominal radiographs or renal ultrasonographic examinations. If calculi are growing or become symptomatic, intervention should be undertaken. Renal calculi < 1.5 cm in diameter are best treated with SWL. Calculi located in the inferior calix frequently result in suboptimal stone-free rates as measured at 3 months by x-ray. Such calculi and others of larger diameter are best treated via percutaneous nephrolithotomy. Percutaneous nephrolithotomy is performed by inserting a needle into the appropriate renal calyx and dilating a tract large enough to allow a nephroscope to pass and inspect, fragment, and remove stone and stone fragments. Perioperative antibiotic coverage should be given on the basis of preoperative urine cultures.

### When to Refer

- Evidence of urinary obstruction.
- Urinary stone with fever.
- Anatomic abnormalities or solitary kidney.
- Concomitant pyelonephritis.

### When to Admit

- Intractable nausea and vomiting or pain.
- Fever.

MALE ERECTILE DYSFUNCTION & SEXUAL DYSFUNCTION

**Essentials of Diagnosis**

- Erectile dysfunction can have organic and psychogenic etiologies.
- Organic erectile dysfunction may be an early sign of cardiovascular disease and requires evaluation.
- Peyronie disease is a common fibrotic disorder of the penile erectile bodies that causes penile deformity and sexual dysfunction.

**General Considerations**

Erectile dysfunction is the consistent inability to attain or maintain a sufficiently rigid penile erection for sexual performance. The condition affects nearly 30 million American men, and its incidence is age related. Approximately 52% of men aged 40–70 years experience erectile dysfunction. Most cases of erectile dysfunction have an organic rather than a psychogenic cause. Normal male erection is a neurovascular event relying on an intact autonomic and somatic nerve supply to the penis, smooth and striated musculature of the corpora cavernosa and pelvic floor, and arterial blood flow supplied by the paired pudendal arteries. Erection is caused and maintained by an increase in arterial flow, active relaxation of the smooth muscle within the sinusoids of the paired corpora cavernosa of the penis, and an increase in venous resistance. Contraction of the bulbocavernosus and ischiocavernosus muscles results in further rigidity of the penis with intracavernosal pressures far exceeding systolic blood pressure. Nitric oxide is a pivotal neurotransmitter that initiates and sustains erections; however, other molecules contribute, including acetycholine, prostaglandins, and vasoactive intestinal peptide.

Male sexual dysfunction may be manifested in a variety of ways, and patient history is critical to the proper classification and treatment. Androgens have a strong influence on the sexual desire of men. A **loss of libido** may indicate androgen deficiency on the basis of either hypothalamic, pituitary, or testicular disease. **Loss of erections** may result from arterial, venous, neurogenic, or psychogenic causes. Concurrent medical problems may damage one or more of the mechanisms. Of particular concern is endothelial dysfunction, defined as the decreased bioavailability of nitric oxide with subsequent impairment of arterial vasodilation. Erectile dysfunction may be an early manifestation of endothelial dysfunction, which precedes more severe, systemic atherosclerotic, cardiovascular disease. In addition, many medications, especially antihypertensive and antidepressant agents, are associated with erectile dysfunction. **Peyronie disease** is a fibrotic disorder of the tunica albuginea of the penis resulting in varying degrees of penile curvature or deformity and sexual dysfunction. Peyronie disease develops in approximately 5% of men older than 50 years, but this may be an underestimate related to embarrassment in seeking care. After onset of the disease, 10% of men improve spontaneously. If left untreated, the disease progresses in half of the remainder and the rest stabilize. Deformity of the penis can be severe enough to impair normal sexual function. The etiology of Peyronie disease is not fully understood and is likely multifactorial. The most promising hypothesis is that subtle penile trauma is followed by abnormal wound healing, although other potential disease modulators may include vascular disease and hypogonadism.

**Priapism** is the occurrence of penile erection unrelated to sexual stimulation, generally lasting longer than 4 hours, and potentially leading to irreversible damage to the erectile mechanisms. Priapism can be due to unregulated high blood flow, but more commonly, it is due to trapping of blood within the erectile bodies resulting in penile ischemia and infarction of the sinusoidal tissue. Priapism may be caused by any of the treatments for erectile dysfunction, drug use, and red blood cell dyscrasias.

**Anejaculation** is the loss of seminal emission and may result from androgen deficiency by decreasing prostate and seminal vesicle secretions as well as sympathetic denervation as a result of diabetes mellitus or pelvic or retroperitoneal surgery or radiation. **Retrograde ejaculation** may occur as a result of mechanical disruption of the bladder neck, especially following transurethral resection of the prostate, pelvic radiation, treatment with α-blockers, or due to sympathetic denervation. If libido and erection are intact, the **loss of orgasm** is usually of psychological origin.

**Premature ejaculation** is the persistent or recurrent ejaculation with minimal stimulation before a person desires (associated with distress) and may be primary or secondary. The former is usually psychogenic in origin and additional history may elucidate the presence of a new partner, unreasonable expectations about performance, or emotional disorders. The latter is caused by erectile dysfunction and may be corrected with erectile dysfunction treatment.

**Clinical Findings**

**A. Symptoms and Signs**

Erectile dysfunction should be distinguished from problems of penile deformity, ejaculation, libido, and orgasm. The severity of the dysfunction (maintaining vs attaining; chronic, occasional, or situational) as well as its timing should be noted. The history should include inquiries about dyslipidemia, hypertension, depression, neurologic disease, diabetes mellitus, chronic kidney disease, and endocrine disorders as well as cardiac or peripheral vascular disease. Pelvic trauma, surgery, or irradiation identifies patients at increased risk for erectile dysfunction. Penile deformity or curvature that prevents normal intercourse should be noted because this may indicate the presence of Peyronie disease, which may complicate treatment. The history should clarify the severity of curvature, loss of penile length, and other deformities that may prevent normal, painless sexual intercourse. It is important to determine whether the patient has any normal erections in the early morning or during sleep. If normal erections occur, an organic cause is less likely. The ability to attain but not maintain an erection may be the first sign of **endothelial dysfunction**, which is the decreased responsiveness of the...
penile vasculature to nitric oxide released from pelvic parasympathetic nerves. The gradual loss of erections over time is more suggestive of an organic cause with the exception of erectile dysfunction that immediately follows pelvic surgery or trauma. Medication use should be noted, since 25% of all cases of sexual dysfunction may be drug related. The use of alcohol, tobacco, and recreational drugs should be recorded, since each is associated with an increased risk of sexual dysfunction.

During the physical examination, secondary sexual characteristics should be assessed. Motor and sensory examination should be performed as well as palpation and quantification of lower extremity vascular pulsations. The genitalia should be examined, noting the presence of penile scarring or plaque formation (Peyronie disease) and any abnormalities in size or consistency of either testicle.

B. Laboratory Findings

Laboratory evaluation should consist of a fasting lipid profile and glucose, testosterone, and prolactin. Patients with abnormalities of testosterone or prolactin require further evaluation with measurement of free testosterone and luteinizing hormone (LH) to distinguish hypothalamic-pituitary dysfunction from testes failure.

C. Special Tests

Further testing is based on the patient’s history and is performed when etiology is unclear. Organic and psychogenic erectile dysfunction frequently occur in tandem, given that erectile dysfunction can contribute to emotional stress. Erectile dysfunction that is primarily psychogenic can generally be differentiated by patient history, whereby men will describe normal nocturnal or morning erections, or situational erectile dysfunction. If the distinction remains unclear, clarity may be gained with the use of nocturnal penile tumescence testing, where the frequency and rigidity of erections are recorded by a tension meter attached to the penis before sleep. Patients with psychogenic erectile dysfunction will have nocturnal erections of adequate frequency and rigidity.

Treatment of patients with oral medications (sildenafil, vardenafil, and tadalafil) provides insight into the etiology and complete penile detumescence. The drugs have variable durations of activity and side effects. Each drug should be initiated at the lowest dose and titrated to effect. There is no effect on libido, and priapism is exceedingly rare. The additive effect of nitrates and phosphodiesterase-5 (PDE-5) inhibitors can contribute to emotional stress. Most men can be treated successfully with one of the approaches outlined below. Men who have psychogenic erectile dysfunction will probably benefit from behaviorally oriented sex therapy.

A. Hormonal Replacement

Testosterone replacement therapy may be offered to men with documented biochemical hypogonadism who have undergone endocrinologic evaluation and in whom there is no evidence of prostate cancer or other contraindication to treatment. Restoration of normal testosterone levels may improve libido and effectiveness of oral erectile medications.

B. Vasoactive Therapy

Sexual stimulation with subsequent nitric oxide release from the parasympathetic nerves and endothelium initiates penile erection. Nitric oxide enters smooth muscles cells, increases cyclic guanosine monophosphate (cGMP) production, which mediates calcium sequestration and cellular hyperpolarization. Phosphodiesterase-5 (PDE-5) degrades cGMP and fosters penile detumescence. Activation of pelvic sympathetic nerves causes ejaculation, contraction of the smooth muscle within the corpora cavernosa and complete penile detumescence.

1. Oral agents—Sildenafil, vardenafil, and tadalafil inhibit PDE-5, preventing the degradation of cGMP, thereby sustaining inflow of blood into the erect penis. The drugs are similarly effective; some patients who do not respond to one PDE-5 inhibitor may respond to one of the other agents. Because of differences in receptor binding affinity and pharmacokinetics, the drugs have variable durations of activity and side effects. Each drug should be initiated at the lowest dose and titrated to effect. There is no effect on libido, and priapism is exceedingly rare. The additive effect of nitrates and phosphodiesterase-5 (PDE-5) inhibitors can contribute to emotional stress. The greatest risk for this effect is within the first hour after taking sildenafil but this risk period may be longer for tadalafil due to increased drug half-life. All patients being evaluated for acute chest pain should be asked if they are taking a PDE-5 inhibitor before administering nitroglycerin and close monitoring of blood pressure is warranted if there is concern regarding drug overlap. Fixed atherosclerotic disease in the aortoiliac system is associated with diminished efficacy.

The combination of PDE-5 inhibitors and α-receptor blockers (which may be prescribed for lower urinary tract symptoms) may cause a larger reduction in systemic blood pressure than when PDE-5 inhibitors are used alone. However, these two classes of medication may be safely used in combination if they are started in a stepwise fashion, with escalation of dose when there is no evidence of syncope. In select men, combined treatment with PDE-5 inhibitors and testosterone replacement may be warranted, since adequate androgen levels may be required for the penile vasculature to be fully responsive to vasoactive drugs.

2. Injectable agents—Direct injection of vasoactive prostaglandins with or without papaverine or phentolamine into the penis is an acceptable form of treatment for many men
with erectile dysfunction. Injections are performed using a tuberculin syringe or a metered-dose injection device. The base and lateral aspect of the penis is used as the injection site to avoid injury to the superficial blood supply located anteriorly. Complications are rare and include bruising, dizziness, local pain, fibrosis, priapism, and infection. Vasoactive prostaglandins (alprostadil) can also be delivered via a urethral suppository with slightly less effectiveness.

The presence of a prolonged erection (priapism) requires immediate medical attention to prevent erectile dysfunction and fibrosis of the cavernosal tissues. Initial management may include aspiration of blood from the penis or injection of sympathomimetic drugs (epinephrine or phentolamine); if these maneuvers fail, surgical shunts may need to be performed to drain blood from the corpora cavernosa.

C. Vacuum Erection Device

The vacuum erection device causes erection by creating a vacuum chamber around the penis, whereby blood is drawn into the corpora cavernosa. Once adequate tumescence has been achieved, an elastic constriction band is placed around the proximal penile shaft to prevent loss of erection, and the vacuum cylinder is removed. Such devices are highly effective, regardless of the cause of erectile dysfunction; however, the devices are cumbersome with a high rate of discontinued use. Complications are rare.

D. Penile Prostheses

Prosthetic devices may be implanted directly into the paired corporal bodies. Penile prostheses may be semi-rigid (malleable) or inflatable. Each is manufactured in a variety of sizes and is custom-fit to the individual. Even for men with normal erectile function, the penis is flaccid 90% of time; therefore, inflatable devices may result in a more natural appearance and better functionality. Complications are rare but include mechanical failure, infection, and injury to adjacent anatomic structures during surgery. For men who elect this treatment, personal and partner satisfaction rates exceed 90%.

E. Vascular Reconstruction

Patients with disorders of the arterial system are candidates for various forms of arterial reconstruction, including endarterectomy and balloon dilation for proximal arterial occlusion and arterial bypass procedures utilizing arterial (epigastric) or venous (deep dorsal vein) segments for distal occlusion. Patients with venous disorders may be managed with ligation of certain veins (deep dorsal or emissary veins) or the crura of the corpora cavernosa. Experience with vascular reconstructive procedures is limited, and many patients so treated still fail to achieve a rigid erection.

F. Medical and Surgical Therapy for Peyronie Disease

A wide range of medical and surgical treatments have been used to treat the disorder. There are no oral therapies for Peyronie disease that are approved by the FDA; however, evidence from randomized controlled trials supports the use of pentoxifylline, coenzyme Q10, colchicine, potassium aminobenzoate (Potaba), and L-carnitine. The intraplate injection of verapamil or interferon improves penile deformity in some patients. Surgical treatment is an alternative for men with compromised sexual function due to severe curvature or lesions causing penile instability. The choice of corrective procedure should be tailored to each patient after a detailed evaluation of disease severity and sexual function.

When to Refer

- Patients with inadequate response to oral medications or who are unable to tolerate side effects.
- Patients with Peyronie disease (penile curvature) or other penile deformity.
- Patients with a history of pelvic or perineal trauma, surgery, or radiation.
- Young patients or those with lifelong erectile dysfunction.
- Ischemic priapism is a medical emergency and requires immediate referral to a urologist or the emergency department for intervention to allow restoration of penile blood perfusion.

MALE INFERTILITY

Couple infertility is related to the male partner in 50% of cases.

Causes include decreased or absent sperm production or function, or obstruction of the male genital tract.

Detailed history, physical examination, and repeated semen analysis are the cornerstones of diagnosis and treatment.

In select men, abnormal semen quality may indicate poor somatic health and increased risk for certain health conditions.
Infertility, the inability of a couple to conceive a child after 1 year of sexual intercourse without contraceptive use, affects 15–20% of US couples. Approximately one-third of cases result from male factors, one-third from female factors, and one-third from combined factors; therefore, evaluation of both partners is critical. Clinical evaluation is warranted following 6 months of unprotected intercourse in select couples. Following a detailed history and physical examination, a semen analysis is essential for diagnosis and should be performed at least twice, on two separate occasions (Figure 23–1). Because spermatogenesis takes approximately 74 days, it is important to review events from the past 3 months. Some types of male infertility put men at higher risk for the later development of testicular germ cell cancer; thus, they should be counseled appropriately and taught self testicular exam.

Clinical Findings

A. Symptoms and Signs

The history should include prior testicular insults (torsion, cryptorchidism, trauma), infections (mumps orchitis, epididymitis), environmental factors (excessive heat, radiation, chemotherapy, prolonged pesticide exposure), medications (anabolic steroids, cimetidine, and spironolactone may affect spermatogenesis; phenytoin may lower FSH; sulfasalazine and nitrofurantoin affect sperm motility), and drugs (alcohol, tobacco, marijuana). Sexual habits, frequency and timing of intercourse, use of lubricants, and each partner’s previous fertility experiences are important. Loss of libido and headaches, visual disturbances, or galactorrhea may indicate a pituitary tumor. The past medical or surgical history may reveal thyroid or liver disease (abnormalities of spermatogenesis), diabetic neuropathy (retrograde or anejaculation), radical pelvic or retroperitoneal surgery (absent seminal emission secondary to sympathetic nerve injury), or hernia repair (damage to the vas deferens or testicular blood supply).

Physical examination should pay particular attention to features of hypogonadism: underdeveloped secondary sexual characteristics, diminished male pattern hair distribution (axillary, body, facial, pubic), body habitus, and gynecomastia. The scrotal contents should be carefully evaluated. Testicular size should be noted (normal size approximately 4.5 × 2.5 cm, volume 18 mL). Varicoceles...
are abnormally dilated and refluxing veins of the pampiniform plexus that can be identified in the standing position by gentle palpation of the spermatic cord and, on occasion, may only be appreciated with the Valsalva maneuver. The vas deferens, epididymis, and prostate should be palpated (absence of all or part of the vas deferens may indicate the presence a cystic fibrosis variant, congenital bilateral or unilateral absence of the vas deferens).

**B. Laboratory Findings**

Semen analysis should be performed after 2 to 3 days of ejaculatory abstinence. The specimen should be analyzed within 1 hour after collection. Abnormal sperm concentrations are <15 million/mL (oligozoospermia is the presence of <15 million sperm/mL in the ejaculate; azoospermia is the absence of sperm). Normal semen volumes range between 1.5 mL and 5 mL (volumes <1.5 mL may result in inadequate buffering of the vaginal acidity and may be due to retrograde ejaculation, ejaculatory duct obstruction, or androgen insufficiency). Normal sperm motility and morphology demonstrate >45% motile cells and >4% normal morphology (World Health Organization). Abnormal motility may result from varicocele, antisperm antibodies, infection, abnormalities of the sperm flagella, or partial ejaculatory duct obstruction. Abnormal morphology may result from a varicocele, infection, or exposure to gonadotoxins (eg, tobacco smoke).

Endocrine evaluation is warranted if sperm counts are low (<15 million/mL) or if there is a basis from the history and physical examination for suspecting an endocrinologic origin. Initial testing should include serum FSH and testosterone. Specific abnormalities in these hormones should prompt additional testing, including LH and prolactin. Elevated FSH and LH levels and low testosterone levels (hypergonadotropic hypogonadism) are associated with primary testicular failure. Low FSH and LH associated with low testosterone occur in secondary testicular failure (hypogonadotropic hypogonadism) and may be of hypothalamic or pituitary origin. Elevation of serum prolactin may indicate the presence of pituitary prolactinoma.

**C. Genetic Testing**

Men with sperm concentrations <10 million/mL should undergo testing for Y chromosome microdeletions and karyotypic abnormalities. Gene deletions from the long arm of the Y chromosome may cause azoospermia or oligozoospermia with age-related decline in spermatogenesis that is transmissible to male offspring. Karyotyping may reveal Klinefelter syndrome. Partial or complete absence of the vas deferens should prompt testing for cystic fibrosis mutations.

**D. Imaging**

Scrotal ultrasound may detect a subclinical varicocele. Vasography may be required in patients with suspected genital duct obstruction. Men with low ejaculate volume and no evidence of retrograde ejaculation should undergo transrectal ultrasound to evaluate the prostate and seminal vesicles. MRI of the sella turcica should be performed in men with markedly elevated prolactin or hypogonadotropic hypogonadism to evaluate the anterior pituitary gland. MRI of the pelvis and scrotum should be considered in men for whom the testes cannot be identified in the scrotum by physical examination or ultrasound.

**E. Special Tests**

Patients with low volume ejaculate should have post-ejaculation urine samples centrifuged and analyzed for sperm to evaluate for retrograde ejaculation. In cases of disproportionately low motility, sperm vitality and the presence of autoantibodies should be assessed. Rounds cells in concentrations >1 million/mL should prompt leukocyte esterase or peroxidase staining (immature germ cells are found normally, but inflammatory cells may require treatment).

**Treatment**

**A. General Measures**

Education about the proper timing for intercourse in relation to the woman’s ovulatory cycle as well as the avoidance of spermicidal lubricants should be discussed. In cases of gonadotoxic exposure or medication-related factors, the offending agent should be removed. Patients with active genitourinary tract infections should be treated with appropriate antibiotics. Healthy lifestyle habits, including healthy diet, moderate exercise, and avoidance of gonadotoxins (such as tobacco smoke) should be reinforced.

**B. Varicocele**

Varicocelectomy is performed by stopping retrograde blood flow in spermatic cord veins. Surgical ligation may be accomplished via subinguinal, inguinal, retroperitoneal, or laparoscopic approaches. Percutaneous venographic embolization of varicoceles is feasible but may have a higher recurrence rate.

**C. Endocrine Therapy**

Hypogonadotropic hypogonadism may be treated with chorionic gonadotropin once primary pituitary disease has been excluded or treated. Dosage is usually 2000 international units intramuscularly three times a week. If sperm counts fail to rise after 12 months, FSH therapy should be initiated.

**D. Ejaculatory Dysfunction Therapy**

Patients with retrograde ejaculation may benefit from α-adrenergic agonists (pseudoephedrine, 60 mg orally three times a day) or imipramine (25 mg orally three times a day). Medical failures may require the collection of post-ejaculation urine for intrauterine insemination. Anejaculation can be treated with vibratory stimulation or electroejaculation in select cases.

**E. Ductal Obstruction**

Obstruction of the ejaculatory ducts may be corrected by transurethral resection of the ducts in the prostatic urethra.
If obstruction of the vas deferens or epididymis is suspected, the level of obstruction must be determined via a vasogram prior to operative treatment, with the exception of prior vasectomy. Obstruction of the vas deferens is best managed by microsurgical vasovasostomy or vasectomy.

F. Assisted Reproductive Techniques

Intrauterine insemination, in vitro fertilization, and intra-cytoplasmic sperm injection (ICSI) are alternatives for patients in whom other means of treating reduced sperm concentration, motility, or functionality has failed. With the use of ICSI, azoospermic men can father their genetic progeny by surgical retrieval of sperm from the testicle, epididymis, or vas deferens.

When to Refer

- Couples with clinical infertility or concern about fertility potential.
- Men with known genital insults, genetic diagnoses, or syndromes that preclude natural fertility.
- Reproductive-aged men with newly diagnosed cancer or other disease that may require cytotoxic therapies with interest in fertility preservation.

Clinical Findings

A. Symptoms

The symptoms of benign prostatic hyperplasia can be divided into obstructive and irritative complaints. Obstructive symptoms include hesitancy, decreased force and caliber of the stream, sensation of incomplete bladder emptying, double voiding (urinating a second time within 2 hours), straining to urinate, and postvoid dribbling. Irritative symptoms include urgency, frequency, and nocturia.

The American Urological Association (AUA) symptom index (Table 23–4) is perhaps the single most important tool used in the evaluation of patients with this disorder and should be calculated for all patients before starting therapy. The answers to seven questions quantitate the severity of obstructive or irritative complaints on a scale of 0–5. Thus, the score can range from 0 to 35, in increasing severity of symptoms.

A detailed history focusing on the urinary tract should be obtained to exclude other possible causes of symptoms such as prostate cancer or disorders unrelated to the prostate such as urinary tract infection, neurogenic bladder, or urethral stricture.

B. Signs

A physical examination, digital rectal examination (DRE), and a focused neurologic examination should be performed on all patients. The size and consistency of the prostate should be noted, but prostate size does not correlate with the severity of symptoms or the degree of obstruction. Benign prostatic hyperplasia usually results in a smooth, firm, elastic enlargement of the prostate. Induration, if detected, must alert the clinician to the possibility of cancer, and further evaluation is needed (ie, prostate-specific antigen [PSA] testing, transrectal ultrasound, and biopsy). Examination of the lower abdomen should be performed to assess for a distended bladder.

C. Laboratory Findings

Urineysis should be performed to exclude infection or hematuria. A serum PSA is considered optional, yet most clinicians will include it in the initial evaluation, particularly if life expectancy is > 10 years. PSA certainly increases

Benign Prostatic Hyperplasia

---

**Essentials of Diagnosis**

- Obstructive or irritative voiding symptoms.
- May have enlarged prostate on rectal examination.
- Absence of urinary tract infection, neurologic disorder, stricture disease, prostatic or bladder malignancy.

**General Considerations**

Benign prostatic hyperplasia is the most common benign tumor in men, and its incidence is age related. The prevalence of histologic benign prostatic hyperplasia in autopsy studies rises from approximately 20% in men aged 41–50 years, to 50% in men aged 51–60, and to over 90% in men over 80 years of age. Although clinical evidence of disease occurs less commonly, symptoms of prostatic obstruction are also age related. At age 55 years, approximately 25% of men report obstructive voiding symptoms. At age 75 years, 50% of men report a decrease in the force and caliber of the urinary stream.

Risk factors for the development of benign prostatic hyperplasia are poorly understood. Some studies have suggested a genetic predisposition and some have noted racial differences. Approximately 50% of men under age 60 years who undergo surgery for benign prostatic hyperplasia may have a heritable form of the disease. This form is most likely an autosomal dominant trait, and first-degree male relatives of such patients carry an increased relative risk of approximately fourfold.

---

commonly associated with bladder stones. Carcinoma of the prostate may be detected by abnormalities on the DRE or an elevated PSA (see Chapter 39 for Prostate Cancer). A urinary tract infection can mimic the irritative symptoms of benign prostatic hyperplasia and can be readily identified by urinalysis and culture; however, a urinary tract infection can also be a complication of benign prostatic hyperplasia. Carcinoma of the bladder, especially carcinoma in situ, may also present with irritative voiding complaints; however, urinalysis usually shows evidence of hematuria (see Chapter 39 for Bladder Cancer). Patients with a neurogenic bladder may also have many of the same symptoms and signs as those with benign prostatic hyperplasia; however, a history of neurologic disease, stroke, diabetes mellitus, or back injury may be obtained, and diminished perineal or lower extremity sensation or alterations in rectal sphincter tone or the bulbocavernosus reflex might be observed on examination. Simultaneous alterations in bowel function (constipation) might also suggest the possibility of a neurologic disorder.

D. Imaging

Upper tract imaging (CT or renal ultrasound) is recommended only in the presence of concomitant urinary tract disease or complications from benign prostatic hyperplasia (ie, hematuria, urinary tract infection, chronic kidney disease, history of stone disease).

E. Cystoscopy

Cystoscopy is not recommended to determine the need for treatment but may assist in determining the surgical approach in patients opting for invasive therapy.

F. Additional Tests

Cystometrograms and urodynamic profiles should be reserved for patients with suspected neurologic disease or those who have failed prostate surgery. Flow rates, postvoid residual urine determination, and pressure-flow studies are considered optional.

Differential Diagnosis

A history of prior urethral instrumentation, urethritis, or trauma should be elucidated to exclude urethral stricture or bladder neck contracture. Hematuria and pain are commonly associated with bladder stones. Carcinoma of the prostate may be detected by abnormalities on the DRE alone; however, because there is much overlap between levels seen in benign prostatic hyperplasia and prostate cancer, its use remains controversial (see below in the section on screening for prostate cancer).

¹90% confidence interval.
²Most of the data reviewed for finasteride are derived from three trials that have required an enlarged prostate for entry. The chance of improvement in men with symptoms yet minimally enlarged prostates may be much less, as noted from the VA Cooperative Trial.
TUIP, transurethral incision of the prostate; TURP, transurethral resection of the prostate.
Patients with mild symptoms (AUA scores 0–7) should be managed by watchful waiting only. Absolute surgical indications are refractory urinary retention (failing at least one attempt at catheter removal), large bladder diverticula, or any of the following sequelae of benign prostatic hyperplasia: recurrent urinary tract infection, recurrent gross hematuria, bladder stones, or chronic kidney disease.

A. Watchful Waiting

The risk of progression or complications is uncertain. However, in men with symptomatic disease, it is clear that progression is not inevitable and that some men undergo spontaneous improvement or resolution of their symptoms.

Retrospective studies on the natural history of benign prostatic hyperplasia are inherently subject to bias, relating in part to patient selection and also to the type and extent of follow-up. Very few prospective studies addressing the natural history have been reported. One small series demonstrated that approximately 10% of symptomatic men may progress to urinary retention while 50% of patients demonstrate marked improvement or resolution of symptoms. A large randomized study compared finasteride with placebo in men with moderate to severely symptomatic disease and enlarged prostates on DRE. Patients in the placebo arm demonstrated a 7% risk of developing urinary retention over 4 years.

Men with moderate or severe symptoms can also be observed if they so choose. The optimal interval for follow-up is not defined, nor are the specific end points for intervention.

B. Medical Therapy

1. α-Blockers—α-Blockers can be classified according to their receptor selectivity as well as their half-life (Table 23–6).

Prazosin is effective; however, it requires dose titration and twice daily dosing. Typical side effects include orthostatic hypotension, dizziness, tiredness, retrograde ejaculation, rhinitis, and headache.

Long-acting α-blockers allow for once-a-day dosing, but dose titration is still necessary because side effects similar to those seen with prazosin may occur. Terazosin improves symptoms and in numerous studies is superior to placebo or finasteride. Terazosin is started at a dosage of 1 mg orally daily for 3 days, increased to 2 mg orally daily for 11 days, then 5 mg orally daily. Additional dose escalation to 10 mg orally daily can be performed if necessary. Doxazosin is started at a dosage of 1 mg orally daily for 7 days, increased to 2 mg orally daily for 7 days, then 4 mg orally daily. Additional dose escalation to 8 mg orally daily can be performed if necessary. Alfuzosin is a long-acting α-blocker; its dose is 10 mg orally once daily and does not require titration.

α1-Blockers are localized to the prostate and bladder neck. Selective blockade of these receptors results in fewer systemic side effects than α-blocker therapy (orthostatic hypotension, dizziness, tiredness, rhinitis, and headache), thus obviating the need for dose titration. The typical dose of tamsulosin is 0.4 mg orally taken 30 minutes after a meal. Several randomized, double-blind, placebo-controlled trials have been performed comparing terazosin, doxazosin, tamsulosin, and alfuzosin with placebo. All agents have demonstrated safety and efficacy. However, floppy eye syndrome, a complication of cataract surgery, can occur in patients taking α-blockers and α1-blockers.

2. 5α-Reductase inhibitors—Finasteride is a 5α-reductase inhibitor that blocks the conversion of testosterone to dihydrotestosterone. This drug impacts upon the epithelial component of the prostate, resulting in reduction in size of the gland and improvement in symptoms. Six months of therapy is required for maximum effects on prostate size (20% reduction) and symptomatic improvement.

Several randomized, double-blind, placebo-controlled trials have been performed comparing finasteride with placebo. Efficacy, safety, and durability are well established. However, symptomatic improvement is seen only in men with enlarged prostates (≥ 40 mL by ultrasonographic examination). Side effects include decreased libido, decrease in volume of ejaculate, and erectile dysfunction. Serum PSA is reduced by approximately 50% in patients receiving finasteride therapy. Therefore, in order to compare with pre-finasteride levels, the serum PSA of a patient taking α-blockers and α1-blockers.

A report suggests that finasteride therapy may decrease the incidence of urinary retention and the need for operative treatment in men with enlarged prostates and moderate to severe symptoms. The larger the prostate over 40 mL, the greater the relative-risk reduction. However, optimal identification of appropriate patients for prophylactic therapy remains to be determined. Dutasteride is a dual 5α-reductase inhibitor that appears to be similar to finasteride in its effectiveness; its dose is 0.5 mg orally daily.

Both finasteride and dutasteride have been shown to be effective chemopreventive agents for prostate cancer in large, randomized clinical trials. The 25% risk reduction was observed in men with both low and high risk for prostate cancer. However, despite the strength of the evidence for 5α-reductase inhibitors in reducing the risk of prostate cancer.

</table>
cancer, an FDA advisory committee recommended against labeling these agents for prostate cancer chemoprevention, citing the potential increased risk of high-grade tumors in these studies, isolated risk reduction in low-grade tumors, and inability to apply the findings to the general population. Moreover, the FDA has included the increased risk of being diagnosed with high-grade prostate cancer in the labels of all 5α-reductase inhibitors.

3. Phosphodiesterase-5 inhibitor—The FDA approved the use of tadalafil to treat the signs and symptoms of benign prostatic hyperplasia in 2011; it is also approved for use in men with both urinary symptoms and erectile dysfunction. The data from two randomized, double-blind, placebo-controlled trials demonstrated significant improvements in standardized measurements of urinary function between 2 and 4 weeks after initiating treatment at 5 mg, with minimal adverse effects.

4. Combination therapy—The four-arm Veterans Administration Cooperative Trial compared placebo, finasteride alone, terazosin alone, and combination of finasteride and terazosin. Over 1200 patients participated, and significant decreases in symptom scores and increases in urinary flow rates were seen only in the arms containing terazosin. However, enlarged prostates were not an entry criterion; in fact, prostate size in this study was much smaller than in previous controlled trials using finasteride (32 versus 52 mL). Other randomized, placebo-controlled trials comparing finasteride with placebo in men with lower urinary tract symptoms and large prostates showed finasteride to be beneficial for reducing symptoms, increasing urinary flow rate, and reducing the risk of complications due to benign prostatic hyperplasia as well as reducing the number of men who required surgery for benign prostatic hyperplasia. The Medical Therapy of Prostatic Symptoms (MTOPS) trial is a large, randomized, placebo-controlled trial comparing finasteride, doxazosin, the combination of the two, and placebo in 3047 men observed for a mean of 4.5 years. Long-term combination therapy with doxazosin and finasteride was safe and reduced the risk of overall clinical progression of benign prostatic hyperplasia significantly more than did treatment with either drug alone. Combination therapy and finasteride alone reduced the long-term risk of acute urinary retention and the need for invasive therapy. Combination therapy had the risks of additional side effects and the cost of two medications.

5. Phytotherapy—Phytotherapy is the use of plants or plant extracts for medicinal purposes. Its use in benign prostatic hyperplasia has been popularized by patient-driven enthusiasm. Several plant extracts have been popularized, including the saw palmetto berry, the bark of Pygeum africanum, the roots of Echinacea purpurea and Hypoxis rooperi, pollen extract, and the leaves of the trembling poplar. The mechanisms of action of these agents are unknown. A 2006 prospective, randomized, double-blind, placebo-controlled trial revealed no improvement in symptoms, urinary flow rate, or quality of life for men with benign prostatic hyperplasia with saw palmetto treatment compared with placebo.

C. Conventional Surgical Therapy
1. Transurethral resection of the prostate (TURP)—Ninety-five percent of simple prostatectomies can be performed endoscopically (TURP). Most of these procedures are performed under a spinal anesthetic and require a 1- to 2-day hospital stay. Symptom scores and flow rate improvement are superior following TURP relative to any minimally invasive therapy; however, the length of the hospital stay is greater. Much controversy revolves around possible higher rates of morbidity and mortality associated with TURP in comparison with open surgery, but the higher rates observed in one study probably related to more significant comorbidities in the TURP patients compared with the patients who received open surgical treatment. Several other studies could not confirm the difference in mortality when controlling for age and comorbidities. The risks of TURP include retrograde ejaculation (75%), erectile dysfunction (5–10%), and urinary incontinence (< 1%). Complications include bleeding, urethral stricture or bladder neck contracture, perforation of the prostate capsule with extravasation, and, if severe, transurethral resection syndrome, a hypovolemic, hyponatremic state resulting from absorption of the hypotonic irrigating solution. Clinical manifestations of the syndrome include nausea, vomiting, confusion, hypertension, bradycardia, and visual disturbances. The risk of transurethral resection syndrome increases with resection times over 90 minutes. Treatment includes diuresis and, in severe cases, hypertonic saline administration (see Hyponatremia, Chapter 21).

2. Transurethral incision of the prostate (TUIP)—Men with moderate to severe symptoms and small prostates often have posterior commissure hyperplasia or an “elevated bladder neck.” These patients will benefit from incision of the prostate. The procedure is more rapid and less morbid than TURP. Outcomes in well-selected patients are comparable, though a lower rate of retrograde ejaculation has been reported (25%).

3. Open simple prostatectomy—When the prostate is too large to remove endoscopically, open enucleation is necessary. What size is “too large” depends upon the surgeon’s experience with TURP. Glands over 100 g are usually considered for open enucleation. In addition to size, other relative indications for open prostatectomy include concomitant bladder diverticulum or bladder stone and whether dorsal lithotomy positioning is or is not possible.

Open prostatectomies can be performed with either a suprapubic or retropubic approach. Simple suprapubic prostatectomy is performed transvesically and is the operation of choice if there is concomitant bladder pathology. After the adenoma is removed, both a urethral and a suprapubic catheter are inserted prior to closure.

In simple retropubic prostatectomy, the bladder is not entered but rather a transverse incision is made in the surgical capsule of the prostate and the adenoma is enucleated as described above; only a urethral catheter is needed at the end of the case.
D. Minimally Invasive Therapy

1. Laser therapy—Several coagulation necrosis techniques have been utilized. Transurethral laser-induced prostatectomy (TULIP) is performed under transrectal ultrasound guidance. The instrument is placed in the urethra and transrectal ultrasound is used to direct the device as it is slowly pulled from the bladder neck to the apex. The depth of treatment is monitored with ultrasound.

Most urologists prefer to use visually directed laser techniques. Visual coagulative necrosis is performed under cystoscopic control, and the laser fiber is pulled through the prostate at several designated areas depending upon the size and configuration of the gland. Four-quadrant and sextant approaches have been described for lateral lobes, with additional treatments directed at enlarged median lobes. Coagulative techniques do not create an immediate visual defect in the prostatic urethra—tissue is sloughed over the course of several weeks up to 3 months following the procedure.

Visual contact ablative techniques take longer in the operating room because the fiber is placed in direct contact with the prostate tissue, which is vaporized. Photovaporization of the prostate (PVP), an alternative laser technique, uses a high-power KTP laser. An immediate defect is obtained in the prostatic urethra, similar to that seen during TURP.

Interstitial laser therapy places fibers directly into the prostate, usually under cystoscopic control. Irritative voiding symptoms may be less in these patients as the urethral mucosa is spared and prostate tissue is resorbed by the body rather than sloughed.

Advantages to laser surgery include minimal blood loss, rare occurrence of transurethral resection syndrome, the ability to treat patients while on anticoagulation therapy, and outpatient surgery. Disadvantages are the lack of tissue for pathologic examination, the longer postoperative catheterization time, the more frequent irritative voiding complaints, and the expense of laser fibers and generators.

Large multicenter, randomized studies with long-term follow-up are needed in comparing laser prostate surgery with TURP and other forms of minimally invasive surgery.

2. Transurethral needle ablation of the prostate (TUNA)—This procedure uses a specially designed urethral catheter that is passed into the urethra. Interstitial radiofrequency needles are then deployed from the tip of the catheter, piercing the mucosa of the prostatic urethra. Radiofrequencies are then used to heat the tissue, resulting in coagulative necrosis. Bladder neck and median lobe enlargement are not well treated by TUNA. Subjective and objective improvement in voiding occurs. In randomized trials comparing TUNA to TURP, similar improvement was seen when comparing life scores, peak urinary flow rates, and postvoid residual urine.

3. Transurethral electrovaporization of the prostate—This technique uses the standard resectoscope. High current densities result in heat vaporization of tissue, creating a cavity in the prostatic urethra. Because the device requires slower sweeping speeds over the prostatic urethra and the depth of vaporization is approximately one-third of a standard loop, this procedure usually takes longer than a standard TURP. Long-term comparative data are needed.

4. Hyperthermia—Microwave hyperthermia is most commonly delivered with a transurethral catheter. Some devices cool the urethral mucosa to decrease the risk of injury. However, if temperatures do not go above 45 °C, cooling is unnecessary. Symptom score and flow rate improvement are obtained, but (as with laser surgery) large randomized studies with long-term follow-up are needed to assess durability and cost-effectiveness.

When to Refer

- Progression to urinary retention.
- Patient dissatisfaction with medical therapy.
- Need for surgical intervention or further evaluation (cystoscopy).

Headache is such a common complaint and can occur for so many different reasons that its proper evaluation may be difficult. New, severe, or acute headaches are more likely than chronic headaches to relate to an intracranial disorder; the approach to such headaches is discussed in Chapter 2. Chronic headaches may be primary or secondary to another disorder. Common primary headache syndromes include migraine, tension-type headache, and cluster headache. Important secondary causes to consider include intracranial lesions, head injury, cervical spondylosis, dental or ocular disease, temporomandibular joint dysfunction, sinusitis, hypertension, depression, and a wide variety of general medical disorders. Although underlying structural lesions are not present in most patients presenting with headache, it is nevertheless important to bear this possibility in mind. About one-third of patients with brain tumors, for example, present with a primary complaint of headache.

The intensity, quality, and site of pain—and especially the duration of the headache and the presence of associated neurologic symptoms—may provide clues to the underlying cause. Migraine headaches are often described as pulsating or throbbing; a sense of tightness or pressure is common with tension headache. Sharp lancinating pain suggests a neuritic cause; ocular or periorbital icepick-like pains occur with migraine or cluster headache; and a dull or steady headache is typical of an intracranial mass lesion. Ocular or periocular pain suggests an ophthalmologic disorder; band-like pain is common with tension headaches; and lateralized headache is common with migraine or cluster headache. In patients with sinusitis, there may be tenderness of overlying skin and bone. With intracranial mass lesions, headache may be focal or generalized; in patients with trigeminal or glossopharyngeal neuralgia, the pain is localized to one of the divisions of the trigeminal nerve or to the pharynx and external auditory meatus, respectively.

Inquiry should be made of precipitating factors. Recent sinusitis, dental surgery, head injury, or symptoms suggestive of a systemic viral infection may suggest the underlying cause. Migraine may be exacerbated by emotional stress, fatigue, foods containing nitrite or tyramine, or the menstrual period. Alcohol may precipitate cluster headache. Temporomandibular joint dysfunction causes headache or facial pain that comes on with chewing; trigeminal or glossopharyngeal neuralgia may also be precipitated by chewing, and masticatory claudication sometimes occurs with giant cell arteritis. Cough-induced headache occurs with structural lesions of the posterior fossa, but in many instances no specific cause can be found.

The timing of symptoms is important. Headaches are typically worse on awakening in patients with an intracranial mass or sleep apnea. Cluster headaches tend to occur at the same time each day or night. Tension headaches are worse with stress or at the end of the day.

Associated symptoms may also be helpful. Nausea; sensitivity to light, sound, and exertion; and a proclivity to retreat to a dark, quiet room typify migraine. Anxiety, agitation, and even suicidality may accompany cluster headache. Other accompanying symptoms may point to specific disorders.

A progressive headache disorder, new onset of headache in middle or later life, headaches that disturb sleep or are related to exertion, and headaches that are associated with neurologic symptoms or a focal neurologic deficit usually require cranial MRI or CT scan to exclude an intracranial mass lesion. Signs of meningeal irritation and impairment of consciousness also indicate the need for further investigation (cranial CT scan or MRI and examination of the cerebrospinal fluid) to exclude subarachnoid hemorrhage or meningeal infection. The diagnosis and treatment of primary neurologic disorders associated with headache are considered separately under these disorders.

1. **Migraine**

- Headache, usually pulsatile.
- Pain is typically, but not always, unilateral.
- Nausea, vomiting, photophobia, and phonophobia are common accompaniments.
- An aura of transient neurologic symptoms (commonly visual) may precede head pain.
- Commonly, head pain occurs with no aura.
**General Considerations**

The pathophysiology of migraine probably relates to neurovascular dysfunction. Headache results from the dilatation of blood vessels innervated by the trigeminal nerve caused by release of neuropeptides from parasympathetic nerve fibers approximating these vessels. The probable underlying mechanism is activation of the trigeminal nucleus caudalis, nucleus tractus solitarius, and dorsal raphe nucleus. Imaging studies have revealed changes in brainstem regions involved in sensory modulation, suggesting that migraine relates to a failure of normal sensory processing. Before or simultaneous with symptom onset, regional cerebral blood flow is decreased in the cortex corresponding to the clinically affected area; after one to several hours, hyperemia occurs in this same region. Cortical spreading depression of Leão has been implicated.

**Clinical Findings**

Classic migrainous headache is a lateralized throbbing headache that occurs episodically following its onset in adolescence or early adult life. In many cases, however, the headaches do not conform to this pattern, although their associated features and response to antimigrainous preparations nevertheless suggest that they have a similar basis. In this broader sense, migrainous headaches may be lateralized or generalized, may be dull or throbbing, and are sometimes associated with anorexia, nausea, vomiting, photophobia, phonophobia, osph孕hobia, cognitive impairment, and blurring of vision. They usually build up gradually and may last for several hours or longer. Focal disturbances of neurologic function may precede or accompany the headaches and have been attributed to constriction of branches of the internal carotid artery. Visual disturbances occur commonly and may consist of field defects; of luminous visual hallucinations such as stars, sparks, uniformed light flashes (photopsia), geometric patterns, or zigzags of light; or of some combination of field defects and luminous hallucinations (scintillating scotomas). Other focal disturbances such as aphasia or numbness, paresthesias, clumsiness, dysarthria, dysequilibrium, or weakness in a circumscribed distribution may also occur.

In rare instances, the neurologic or somatic disturbance accompanying typical migrainous headaches becomes the sole manifestation of an attack (“migraine equivalent”). Very rarely, the patient may be left with a permanent neurologic deficit following a migrainous attack, and migraine with aura may be a risk factor for stroke.

Patients often give a family history of migraine. Attacks may be triggered by emotional or physical stress, lack or excess of sleep, missed meals, specific foods (eg, chocolate), alcoholic beverages, bright lights, loud noise, menstruation, or use of oral contraceptives.

An uncommon variant is basilar artery migraine, in which blindness or visual disturbances throughout both visual fields are initially accompanied or followed by dysarthria, dysequilibrium, tinnitus, and perioral and distal paresthesias and are sometimes followed by transient loss of consciousness or by a confusional state. This, in turn, is followed by a throbbing (usually occipital) headache, often with nausea and vomiting.

In **ophthalmoplegic migraine**, lateralized pain—often about the eye—is accompanied by nausea, vomiting, and diplopia due to transient external ophthalmoplegia. The ophthalmoplegic migraine is due to third nerve palsy, sometimes with accompanying sixth nerve involvement, and may last the orbital pain by several days or even weeks. The opthalmic division of the fifth nerve has also been affected in some patients. Ophthalmoplegic migraine is rare; more common causes of a painful ophthalmoplegia are internal carotid artery aneurysms and diabetes.

Migraine often exhibits a complex, polygenic pattern of inheritance. Sometimes, an autosomal dominant inheritance pattern is apparent, as in familial hemiplegic migraine (FHM), in which attacks of lateralized weakness represent the aura. Mutations in three associated genes—**ATP1A2**, **CACNA1A**, and **SCN1A**—account for about three-quarters of cases.

**Treatment**

Management of migraine consists of avoidance of any precipitating factors, together with prophylactic or symptomatic pharmacologic treatment if necessary.

**A. Symptomatic Therapy**

During acute attacks, many patients find it helpful to rest in a quiet, darkened room until symptoms subside. A simple analgesic (eg, aspirin, acetaminophen, ibuprofen, or naproxen) taken right away often provides relief, but treatment with prescription therapy is sometimes necessary. To prevent medication overuse, use of simple analgesics should be limited to 15 days or less per month, and combination analgesics should be limited to no more than 10 days per month.

Cafergot, a combination of ergotamine tartrate (1 mg) and caffeine (100 mg), is often particularly helpful; one or two tablets are taken at the onset of headache or warning symptoms, followed by one tablet every 30 minutes, if necessary, up to six tablets per attack and no more than 10 days per month. Because of impaired absorption or vomiting during acute attacks, oral medication sometimes fails to help. Cafergot given rectally as suppositories (one-half to one suppository containing 2 mg of ergotamine) or dihydroergotamine mesylate (0.5–1 mg intravenously or 1–2 mg subcutaneously or intramuscularly) may be useful in such cases. Ergotamine-containing preparations should be avoided in pregnancy and when cardiovascular disease or risk factors are present. Prochlorperazine, administered rectally (25 mg suppository) or intravenously or orally (5–10 mg) can be an effective alternative, as can the various butalbital-containing combination analgesics available.

Sumatriptan, which has a high affinity for 5-HT<sub>1</sub> receptors, is a rapidly effective agent for aborting attacks when given subcutaneously by an autoinjection device (4–6 mg once subcutaneously, may repeat once after 2 hours if needed; maximum dose 12 mg/24 h). Nasal and oral preparations are available but may be less effective due to slower absorption. Zolmitriptan, another selective 5-HT<sub>1</sub> receptor
agonist, has high bioavailability after oral administration and is also effective for the immediate treatment of migraine. The optimal initial oral dose is 5 mg, and relief usually occurs within 1 hour; may repeat once after 2 hours. The maximum dose for both formulations is 10 mg/24 h. A number of other triptans are available, including rizatRIPTAN (5–10 mg orally at onset, may repeat every 2 hours twice [maximum dose 30 mg/24 h]); naratriPTAN (1–2.5 mg orally at onset, may repeat once after 4 hours [maximum dose 5 mg/24 h]); almotriPTAN (6.25–12.5 mg orally at onset, may repeat dose once after 2 hours [maximum dose 25 mg/24 h]); frovatriPTAN (2.5 mg orally at onset, may repeat after 2 hours once [maximum dose 7.5 mg/24]); and eletriptAN (20–40 mg orally at onset; may repeat after 2 hours once [maximum dose 80 mg/24 h]). Eletriptan is useful for immediate therapy and frovatriptAN, which has a longer half-life, may be worthwhile for patients with prolonged attacks or attacks provoked by menstrual periods.

TriptANS may cause nausea and vomiting. They should probably be avoided in women who are pregnant, in patients with hemiplegic or basilar migraine, and in patients with risk factors for stroke (such as hypertension, prior stroke or transient ischemic attack, diabetes mellitus, hypercholesterolemia, obesity). TriptANS are contraindicated in patients with coronary or peripheral vascular disease. Patients often experience greater benefit when the triptan is combined with naproxen (500 mg).

Several non-triptan abortive therapies, including telcagepant (a calcitonin gene-related peptide antagonist) and lasmiditan (a serotonin 1F receptor agonist), are currently in clinical trials and may be better tolerated than triptANS.

The neuroleptic droperidol is also helpful in aborting acute attacks, particularly in an emergency setting in opioid-tolerant patients. Intravenous metoclopramide and prochlorperazine are effective. Opioid analgesics are sometimes required when other therapies fail. Intravenous propofol in subanesthetic doses may help in intractable cases.

### B. Preventive Therapy

Preventive treatment may be necessary if migraine headaches occur more frequently than two or three times a month or significant disability is associated with attacks. Some of the more common drugs used for this purpose are listed in Table 24–1. Their mode of action is unclear but may involve alteration of central neurotransmission. Several drugs may have to be tried in turn before the headaches are brought under control. Once a drug has been found to help, it should be continued for several months. If

<sup>1</sup>Gabapentin and possibly other antiepileptics have also been used successfully.

<sup>2</sup>Avoid during pregnancy.

<sup>3</sup>Not FDA-approved for this indication.

<sup>4</sup>Other calcium channel antagonists (eg, nimodipine, nicardipine, and diltiazem) may also help.

<sup>5</sup>Depression is commonly comorbid with migraine disorder and may warrant separate treatment.

<sup>6</sup>Other tricyclic antidepressants (eg, nortriptyline and imipramine) may similarly help.
the patient remains headache-free, the dose may be tapered and the drug eventually withdrawn. Botulinum toxin type A was approved by the US Food and Drug Administration (FDA) for migraine prevention in late 2010, despite conflicting results regarding its efficacy among randomized, placebo-controlled trials. Although acupuncture has been widely used in the prophylaxis of migraine, a randomized controlled trial failed to show any difference between it and sham acupuncture. Some neurostimulation techniques look promising, including occipital nerve stimulation.

2. Tension-type Headache

This is the most common type of primary headache disorder. Patients frequently complain of pericranial tenderness, poor concentration, and other nonspecific symptoms, in addition to constant daily headaches that are often vise-like or tight in quality but are not pulsatile. Headaches may be exacerbated by emotional stress, fatigue, noise, or glare. The headaches are usually generalized, may be most intense about the neck or back of the head, and are not associated with focal neurologic symptoms. There is diagnostic overlap with migraine.

The therapeutic approach is similar to that in migraine, except that triptan drugs are not indicated. Treatment of comorbid anxiety or depression is important. Techniques to induce relaxation are sometimes useful and include massage, hot baths, and biofeedback.

3. Cluster Headache

Cluster headache affects predominantly middle-aged men. The pathophysiology is unclear but may relate to activation of cells in the ipsilateral hypothalamus, triggering the trigeminal autonomic vascular system. There is often no family history of headache or migraine. Episodes of severe unilateral periorbital pain occur daily for several weeks and are often accompanied by one or more of the following: ipsilateral nasal congestion, rhinorrhea, lacrimation, redness of the eye, and Horner syndrome (ptosis of the eyelid, miosis or constriction of the pupil, and anhidrosis or reduced sweat secretion). During attacks, patients are often restless and agitated. Episodes often occur at night, awaken the patient, and last for between 15 minutes and 3 hours. Spontaneous remission then occurs, and the patient remains well for weeks or months before another bout of closely spaced attacks occurs. Bouts may last for 4 to 8 weeks and may occur up to several times per year. During a bout, many patients report that alcohol triggers an attack; others report that stress, glare, or ingestion of specific foods occasionally precipitates attacks. In occasional patients, remission does not occur. This variant has been referred to as chronic cluster headache. Hemicrania continua is a separate primary headache syndrome with unilateral head pain and associated autonomic symptoms; unlike cluster headache, the pain is continuous without pain-free periods, and it completely resolves with indomethacin.

Examination reveals no abnormality apart from Horner syndrome that either occurs transiently during an attack or, in longstanding cases, remains as a residual deficit between attacks.

Treatment of an individual attack with oral drugs is generally unsatisfactory, but subcutaneous (6 mg dose) or intranasal (20-mg/spray) sumatriptan or inhalation of 100% oxygen (12–15 L/min for 15 minutes via a non-rebreather mask) may be effective. Zolmitriptan (5- and 10-mg nasal spray) is also effective. Dihydroergotamine (0.5–1 mg intramuscularly or intravenously) is sometimes used. Viscous lidocaine (1 mg of 4–6% solution) intranasally is sometimes effective.

Various prophylactic agents that have been found to be effective in individual patients include cimivamide (not available in the United States), lithium carbonate (monitored by plasma lithium determination), verapamil (240–960 mg daily), topiramate (100–400 mg daily), valproate (750–1500 mg daily), and suboccipital corticosteroid injection about the greater occipital nerve. As there is often a delay before these medications are effective, transitional therapy is often used. Ergotamine tartrate is effective and can be given as rectal suppositories (0.5–1 mg at night or twice daily), by mouth (2 mg daily), or by subcutaneous injection (0.25 mg three times daily for 5 days per week). Other options include prednisone (60 mg daily for 5 days followed by gradual withdrawal), or dihydroergotamine (9.25 mg intravenously over several days or 0.5 mg intramuscularly twice daily). Stimulation of the occipital nerve may be helpful.

4. Posttraumatic Headache

A variety of nonspecific symptoms may follow closed head injury, regardless of whether consciousness is lost. Headache is often a conspicuous feature.

The headache itself usually appears within a day or so following injury, may worsen over the ensuing weeks, and then gradually subsides. It is usually a constant dull ache, with superimposed throbbing that may be localized, lateralized, or generalized. It is sometimes accompanied by nausea, vomiting, or scintillating scotomas. Headaches occurring more than 1–2 weeks after the inciting event are probably not directly attributable to the head injury.

Dyssequilibrium, sometimes with a rotatory component, may also occur and is often enhanced by postural change or head movement. Impaired memory, poor concentration, emotional instability, and increased irritability are other common complaints and occasionally are the sole manifestations of the syndrome. The duration of symptoms relates in part to the severity of the original injury, but even trivial injuries are sometimes followed by symptoms that persist for months.

Special investigations are usually not helpful. The electroencephalogram may show minor nonspecific changes, while the electroencephalogram sometimes suggests either peripheral or central vestibulopathy. CT scans or MRI of the head usually show no abnormal findings.

Treatment is difficult, but optimistic encouragement and graduated rehabilitation, depending on the occupational circumstances, are advised as symptoms often resolve spontaneously within several months. Headaches often respond to simple analgesics, but severe headaches may necessitate preventive treatment as outlined for migraine.
5. Primary Cough Headache

Severe head pain may be produced by coughing (and by straining, sneezing, and laughing) but, fortunately, usually lasts for only a few minutes or less. The pathophysiologic basis of the complaint is not known, and often there is no underlying structural lesion. However, intracranial lesions, usually in the posterior fossa (eg, Arnold-Chiari malformation), are present in about 10% of cases, and brain tumors or other space-occupying lesions may present in this way. Accordingly, CT scanning or MRI should be undertaken in all patients and repeated annually for several years, since a small structural lesion may not show up initially.

The disorder is usually self-limited, although it may persist for several years. For unknown reasons, symptoms sometimes clear completely after lumbar puncture. Indomethacin (75–150 mg daily orally) may provide relief. Similar activity-triggered headache syndromes include primary exertional headache and primary headache associated with sexual activity.

6. Headache Due to Giant Cell (Temporal or Cranial) Arteritis

The superficial temporal, vertebral, ophthalmic, and posterior ciliary arteries are often the most severely affected pathologically. Most patients are elderly. The major symptom is lateralized headache, often associated with or preceded by myalgia, malaise, anorexia, weight loss, and other nonspecific complaints. Loss of vision is the most feared complication and occurs quite commonly. Clinical examination often reveals tenderness of the scalp and over the temporal arteries. Further details, including approaches to treatment, are given in Chapter 20.

7. Headache Due to Intracranial Mass Lesions

Intracranial mass lesions of all types may cause headache owing to displacement of vascular structures and other pain-sensitive tissues. Posterior fossa tumors often cause occipital pain, and supratentorial lesions lead to bifrontal headache, but such findings are too inconsistent to be of value in attempts at localizing a pathologic process. The headaches are nonspecific in character and may vary in severity from mild to severe. They may be worsened by exertion or postural change and may be associated with nausea and vomiting, but this is true of migraine also. Headaches are also a feature of pseudotumor cerebri (idiopathic intracranial hypertension) (see below). Signs of focal or diffuse cerebral dysfunction or of increased intracranial pressure will indicate the need for further investigation. Similarly, a progressive headache disorder or the new onset of headaches in middle or later life merits investigation if no cause is apparent.

8. Medication Overuse (Analgesic Rebound) Headache

In approximately half of all patients with chronic daily headaches, medication overuse is responsible. They present with chronic pain or with complaints of severe headache unresponsive to medication. Early initiation of a migraine preventive therapy (see above) permits withdrawal of analgesics and eventual relief of headache.

9. Headache Due to Other Neurologic Causes

Cerebrovascular disease may be associated with headache, but the mechanism is unclear. Headache may occur with internal carotid artery occlusion or carotid dissection and after carotid endarterectomy. Diagnosis is facilitated by the clinical accompaniments and the circumstances in which the headache developed.

Acute severe headache accompanies subarachnoid hemorrhage and meningeal infections; accompanying signs of impairment of consciousness and sign of meningeal irritation indicate the need for further investigations.

Dull or throbbing headache is a frequent sequel of lumbar puncture and may last for several days. It is aggravated by the erect posture and alleviated by recumbency. The exact mechanism is unclear, but it is commonly attributed to leakage of cerebrospinal fluid through the dural puncture site. Its incidence may be reduced if a small-diameter needle is used for the spinal tap, and perhaps also if the patient lies prone or supine after the procedure.

When to Refer

- Acute onset of “worst headache in my life.”
- Increasing headache unresponsive to simple measures.
- History of trauma, hypertension, fever, visual changes.
- Presence of neurologic signs or of scalp tenderness.

When to Admit

- Suspected subarachnoid hemorrhage or structural intracranial lesion.
- Depends on underlying cause.

NERVOUS SYSTEM DISORDERS

1. Trigeminal Neuralgia

ESSENTIALS OF DIAGNOSIS

- Brief episodes of stabbing facial pain.
- Pain is in the territory of the second and third division of the trigeminal nerve.
- Pain exacerbated by touch.

General Considerations

Trigeminal neuralgia (“tic douloureux”) is most common in middle and later life. It affects women more frequently than men.

Clinical Findings

Momentary episodes of sudden lancinating facial pain occur and commonly arise near one side of the mouth and shoot toward the ear, eye, or nostril on that side. The pain may be triggered or precipitated by such factors as touch, movement, drafts, and eating. Indeed, in order to lessen the likelihood of triggering further attacks, many patients try to hold the face still while talking. Spontaneous remissions for several months or longer may occur. As the disorder progresses, however, the episodes of pain become more frequent, remissions become shorter and less common, and a dull ache may persist between the episodes of stabbing pain. Symptoms remain confined to the distribution of the trigeminal nerve (usually the second or third division) on one side only.

Differential Diagnosis

The characteristic features of the pain in trigeminal neuralgia usually distinguish it from other causes of facial pain. Neurologic examination shows no abnormality except in a few patients in whom trigeminal neuralgia is symptomatic of some underlying lesion, such as multiple sclerosis or a brainstem neoplasm, in which case the finding will depend on the nature and site of the lesion. Similarly, CT scans and radiologic contrast studies are often normal in patients with classic trigeminal neuralgia.

In a young patient presenting with trigeminal neuralgia, multiple sclerosis must be suspected even if there are no other neurologic signs. In such circumstances, findings on evoked potential testing and examination of cerebrospinal fluid may be corroborative. When the facial pain is due to a posterior fossa tumor, CT scanning and MRI generally reveal the lesion.

Treatment

The drugs most helpful for treatment are oxcarbazepine (although not approved by the FDA for this indication) or carbamazepine, with monitoring by serial blood counts and liver function tests. If these medications are ineffective or cannot be tolerated, phenytoin should be tried. (Doses and side effects of these drugs are shown in Table 24–3). Baclofen (10–20 mg three or four times daily) or lamotrigine (400 mg orally daily) may also be helpful, either alone or in combination with one of these other agents. Gabapentin may also relieve pain, especially in patients who do not respond to conventional medical therapy and those with multiple sclerosis. Depending on response and tolerance, up to 2400 mg daily orally is given in divided doses.

In the past, alcohol injection of the affected nerve, rhizotomy, or tractotomy was recommended if pharmacologic treatment was unsuccessful. More recently, however, posterior fossa exploration has frequently revealed some structural cause for the neuralgia (despite normal findings on CT scans, MRI, or arteriograms), such as an anomalous artery or vein impinging on the trigeminal nerve root. In such cases, simple decompression and separation of the anomalous vessel from the nerve root produce lasting relief of symptoms. In elderly patients with a limited life expectancy, radiofrequency rhizotomy is sometimes preferred because it is easy to perform, has few complications, and provides symptomatic relief for a period of time. Gamma radiosurgery to the trigeminal root is another noninvasive approach that appears to be successful in most patients, with essentially no side effects other than facial paresthesias in a few instances; up to one-third of patients achieved a pain-free state without need for medication after the procedure. Surgical exploration generally reveals no abnormality and is inappropriate in patients with trigeminal neuralgia due to multiple sclerosis.

2. Atypical Facial Pain

Facial pain without the typical features of trigeminal neuralgia is generally a constant, often burning pain that may have a restricted distribution at its onset but soon spreads to the rest of the face on the affected side and sometimes
involves the other side, the neck, or the back of the head as well. The disorder is especially common in middle-aged women, many of them depressed, but it is not clear whether depression is the cause of or a reaction to the pain. Simple analgesics should be given a trial, as should tricyclic antidepressants, carbamazepine, oxcarbazepine, and phenytoin; the response is often disappointing. Opioid analgesics pose a danger of addiction in patients with this disorder. Attempts at surgical treatment are not indicated.

3. Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is an uncommon disorder in which pain similar in quality to that in trigeminal neuralgia occurs in the throat, about the tonsillar fossa, and sometimes deep in the ear and at the back of the tongue. The pain may be precipitated by swallowing, chewing, talking, or yawning and is sometimes accompanied by syncope. In most instances, no underlying structural abnormality is present; multiple sclerosis is sometimes responsible. Oxcarbazepine and carbamazepine (see Table 24–3) are the treatments of choice and should be tried before any surgical procedures are considered. Microvascular decompression is generally preferred over destructive surgical procedures such as partial rhizotomy in medically refractory cases and is often effective without causing severe complications.

4. Postherpetic Neuralgia

Herpes zoster (shingles) is due to reactivation of a latent varicella-zoster virus infection in a sensory nerve ganglion. Postherpetic neuralgia develops in about 15% of patients who have shingles. This complication seems especially likely to occur in elderly or immunocompromised persons, when the rash is severe, and when the first division of the trigeminal nerve is affected. It also relates to the duration of the rash before medical consultation. A history of shingles and the presence of cutaneous scarring resulting from shingles aid in the diagnosis. Severe pain with shingles correlates with the intensity of postherpetic symptoms.

The incidence of postherpetic neuralgia may be reduced by the treatment of shingles with oral acyclovir or famciclovir, but this is disputed; systemic corticosteroids do not help. Management of the established complication is essentially medical. If simple analgesics fail to help, a trial of a tricyclic antidepressant (eg, amitriptyline, up to 100–150 mg daily orally) is often effective. Other patients respond to carbamazepine (up to 1200 mg daily orally), phenytoin (300 mg daily orally), gabapentin (up to 3600 mg daily orally), or pregabalin (up to 600 mg/daily orally). A combination of gabapentin and morphine taken orally may provide better analgesia at lower doses of each agent than either taken alone. Topical application of capsaicin cream (eg, Zostrix, 0.025%) may be helpful, but a transdermal patch (8%) had no effect. Topical lidocaine (5%) is also worthy of trial. The administration of live-attenuated zoster vaccine to patients over the age of 60 years is important in preventing the occurrence of herpes zoster, although it does not reduce the incidence of postherpetic neuralgia.

5. Facial Pain Due to Other Causes

Facial pain may be caused by temporomandibular joint dysfunction in patients with malocclusion, abnormal bite, or faulty dentures. There may be tenderness of the masticatory muscles, and an association between pain onset and jaw movement is sometimes noted. This pattern differs from that of jaw (masticatory) claudication, a symptom of giant cell arteritis, in which pain develops progressively with mastication. Treatment of the underlying joint dysfunction relieves symptoms.

A relationship of facial pain to chewing or temperature changes may suggest a dental disturbance. The cause is sometimes not obvious, and diagnosis requires careful dental examination and radiographs. Sinusitis and ear infections causing facial pain are usually recognized by the history of respiratory tract infection, fever and, in some instances, nasal or aural discharge. There may be localized tenderness. Radiologic evidence of sinus infection or mastoiditis is confirmatory.

Glaucoma is an important ocular cause of facial pain, usually localized to the periocular region.

On occasion, pain in the jaw may be the principal manifestation of angina pectoris. Precipitation by exertion and radiation to more typical areas establish the cardiac origin.

When to Refer

- Worsening pain unresponsive to simple measures.
- Continuing pain of uncertain cause.
- For consideration of surgical treatment (trigeminal or glossopharyngeal neuralgia).

**EPILEPSY**

- Recurrent seizures.
- Characteristic electroencephalographic changes accompany seizures.
- Mental status abnormalities or focal neurologic symptoms may persist for hours postictally.
Etiology

According to the International League Against Epilepsy classification system, the many etiologies of seizures can be grouped into three categories.

A. Genetic Epilepsy

This category encompasses a broad range of disorders, for which the age at onset ranges from the neonatal period to adolescence or even later in life. Monogenic disorders tend to exhibit an autosomal dominant pattern of inheritance, and where the mutation is known, the responsible gene often encodes a neuronal ion channel.

B. Structural/Metabolic Epilepsy

There are many causes for recurrent seizures.

1. Pediatric age groups—Congenital abnormalities and perinatal injuries may result in seizures presenting in infancy or childhood.

2. Metabolic disorders—Withdrawal from alcohol or drugs is a common cause of recurrent seizures, and other metabolic disorders (such as uremia and hypoglycemia or hyperglycemia) may also be responsible. Since these seizures are provoked by a readily reversible cause, this would not be considered epilepsy.

3. Trauma—Trauma is an important cause of seizures at any age, but especially in young adults. Posttraumatic epilepsy is more likely to develop if the dura mater was penetrated and generally becomes manifest within 2 years following the injury. However, seizures developing in the first week after head injury do not necessarily imply that future attacks will occur. There is no clear evidence that prophylactic anticonvulsant drug treatment reduces the incidence of posttraumatic epilepsy.

4. Tumors and other space-occupying lesions—Neoplasms may lead to seizures at any age, but they are an especially important cause of seizures in middle and later life, when the incidence of neoplastic disease increases. The seizures are commonly the initial symptoms of the tumor and often are focal in character. They are most likely to occur with structural lesions involving the frontal, parietal, or temporal regions. Tumors must be excluded by imaging studies (MRI preferred over CT) in all patients with onset of seizures after 30 years of age, focal seizures or signs, or a progressive seizure disorder.

5. Vascular diseases—Vascular diseases become increasingly frequent causes of seizures with advancing age and are the most common cause of seizures with onset at age 60 years or older.

6. Degenerative disorders—Alzheimer disease and other degenerative disorders are a cause of seizures in later life.

7. Infectious diseases—Infectious diseases must be considered in all age groups as potentially reversible causes of seizures. Seizures may occur with an acute infective or inflammatory illness, such as bacterial meningitis or herpes encephalitis, or in patients with more longstanding or chronic disorders, such as neurosyphilis or cerebral cystercerosis. In patients with AIDS, they may result from central nervous system toxoplasmosis, cryptococcal meningitis, secondary viral encephalitis, or other infective complications. Seizures are a common sequela of supra-tentorial brain abscess, developing most frequently in the first year after treatment.

C. Unknown

In many cases, the cause of epilepsy cannot be determined.

Classification of Seizures

The International League Against Epilepsy distinguishes seizures affecting only part of the brain (focal seizures) from those that are generalized (Table 24–2).

A. Focal Seizures

The initial clinical and electroencephalographic manifestations of partial seizures indicate that only a restricted part of one cerebral hemisphere has been activated. The ictal manifestations depend on the area of the brain involved. Focal seizures sometimes involve impairment of consciousness and may evolve to convulsive seizures, in a process previously called secondary generalization.

1. Without impairment of consciousness—Seizures may be manifested by focal motor symptoms (convulsive jerking) or somatosensory symptoms (eg, paresthesias or tingling) that spread (or “march”) to different parts of the limb or body depending on their cortical representation; such seizures were previously described as “simple partial” seizures. In other instances, special sensory symptoms (eg, light flashes or buzzing) indicate involvement of visual, auditory, olfactory, or gustatory regions of the brain, or there may be autonomic symptoms or signs (eg, abnormal epigastric sensations, sweating, flushing, pupillary dilation). The sole manifestations of some seizures are phenomena such as dysphasia, dysnemetic symptoms (eg, déjà vu, jamais vu), affective disturbances, illusions, or structured hallucinations, but such symptoms are usually accompanied by impairment of consciousness.

2. With impairment of consciousness—Impaired consciousness or responsiveness may be preceded, accompanied, or followed by the various symptoms mentioned above, and automatisms may occur. Such seizures were previously called “complex partial” seizures.

B. Generalized Seizures

There are several different varieties of generalized seizures, as outlined below. In some circumstances, seizures cannot be classified because of incomplete information or because they do not fit into any category.
consciousness, the patient becomes rigid and falls to the ground, and respiration is arrested. This tonic phase, which usually lasts for less than 1 minute, is followed by a clonic phase in which there is jerking of the body musculature that may last for 2 or 3 minutes and is then followed by a stage of flaccid coma. During the seizure, the tongue or lips may be bitten, urinary or fecal incontinence may occur, and the patient may be injured. Immediately after the seizure, the patient may recover consciousness, drift into sleep, have a further convulsion without recovery of consciousness between the attacks (status epilepticus), or after recovering consciousness have a further convulsion (serial seizures). In other cases, patients will behave in an abnormal fashion in the immediate postictal period, without subsequent awareness or memory of events (postepileptic automatism). Headache, disorientation, confusion, drowsiness, nausea, soreness of the muscles, or some combination of these symptoms commonly occurs postictally.

5. Tonic-clonic ("grand mal") seizures—In these seizures, which are characterized by sudden loss of consciousness, the patient becomes rigid and falls to the ground, and respiration is arrested. This tonic phase, which usually lasts for less than 1 minute, is followed by a clonic phase in which there is jerking of the body musculature that may last for 2 or 3 minutes and is then followed by a stage of flaccid coma. During the seizure, the tongue or lips may be bitten, urinary or fecal incontinence may occur, and the patient may be injured. Immediately after the seizure, the patient may recover consciousness, drift into sleep, have a further convulsion without recovery of consciousness between the attacks (status epilepticus), or after recovering consciousness have a further convulsion (serial seizures). In other cases, patients will behave in an abnormal fashion in the immediate postictal period, without subsequent awareness or memory of events (postepileptic automatism). Headache, disorientation, confusion, drowsiness, nausea, soreness of the muscles, or some combination of these symptoms commonly occurs postictally.

### Clinical Findings

#### A. Symptoms and Signs

Non-specific changes such as headache, mood alterations, lethargy, and myoclonic jerking alert some patients to an impending seizure hours before it occurs. These prodromal
symptoms are distinct from the aura; the aura that may precede a generalized seizure by a few seconds or minutes is itself a part of the attack and it arises locally from a restricted part of the brain.

In most patients, seizures occur unpredictably at any time and without any relationship to posture or ongoing activities. Occasionally, however, they occur at a particular time (eg, during sleep) or in relation to external precipitants such as lack of sleep, missed meals, emotional stress, menstruation, alcohol ingestion (or alcohol withdrawal; see below), or use of certain drugs. Fever and nonspecific infections may also precipitate seizures in epileptic patients. In a few patients, seizures are provoked by specific stimuli such as flashing lights or a flickering television set (photosensitive epilepsy), music, or reading.

Clinical examination between seizures shows no abnormality in patients with idiopathic epilepsy, but in the immediate postictal period, extensor plantar responses may be seen. The presence of lateralized or focal signs postictally suggests that seizures may have a focal origin. In patients with symptomatic epilepsy, the findings on examination will reflect the underlying cause.

B. Imaging

MRI is indicated for patients with focal neurologic symptoms or signs, focal seizures, or electroencephalographic findings of a focal disturbance; some clinicians routinely order MRI for all patients with new-onset seizure disorders. CT is generally less sensitive than MRI to small structural brain abnormalities but may be used when MRI is contraindicated (eg, in a patient with a metallic implant). Such studies should be performed in patients with clinical evidence of a progressive disorder and in those with new onset of seizures after the age of 20 years because of the possibility of an underlying neoplasm.

C. Laboratory and Other Studies

Initial investigations should include hematologic and biochemical screening tests (eg, complete blood count, serum glucose, electrolytes, creatinine, calcium, magnesium, and liver function tests). The hematologic and biochemical screening tests are important both to exclude various causes of seizures and to provide a baseline for subsequent monitoring of long-term effects of treatment. A lumbar puncture may be necessary when any sign of infection is present or in the evaluation of new-onset seizures in the acute setting.

Electroencephalography may support the clinical diagnosis of epilepsy (by demonstrating paroxysmal abnormalities containing spikes or sharp waves), may provide a guide to prognosis, and may help classify the seizure disorder. Classification of the disorder is important for determining the most appropriate anticonvulsant drug with which to start treatment. For example, absence and focal seizures with impairment of consciousness may be difficult to distinguish clinically, but the electroencephalographic findings and treatment of choice differ in these two conditions. Finally, by localizing the epileptogenic source, the electroencephalographic findings are important in evaluating candidates for surgical treatment.

### Differential Diagnosis

The distinction between the various disorders likely to be confused with generalized seizures is usually made on the basis of the history. The importance of obtaining an eyewitness account of the attacks cannot be overemphasized.

#### A. Differential Diagnosis of Focal Seizures

1. **Transient ischemic attacks**—These attacks are distinguished from seizures by their longer duration, lack of spread, and symptoms. Level of consciousness, which is unaltered, does not distinguish them. There is a loss of motor or sensory function (eg, weakness or numbness) with transient ischemic attacks, whereas positive symptoms (eg, convulsive jerking or paresthesias) characterize seizures.

2. **Rage attacks**—Rage attacks are usually situational and lead to goal-directed aggressive behavior.

3. **Panic attacks**—These may be hard to distinguish from focal seizures unless there is evidence of an anxiety disorder between attacks and the attacks have a clear relationship to external circumstances.

#### B. Differential Diagnosis of Generalized Seizures

1. **Syncope**—Syncope is defined as a transient loss of consciousness due to postural change, emotional stress, instrumentation, pain, or straining. They are typically preceded by pallor, sweating, nausea, and malaise and lead to loss of consciousness accompanied by flaccidity; recovery occurs rapidly with recumbency, and there is no postictal headache or confusion. In some instances, however, motor accompaniments may simulate a seizure. Serum creatine kinase measured about 3 hours after the event is generally normal after syncopal episodes but markedly elevated after tonic-clonic seizures.

2. **Cardiac disease**—Cerebral hypoperfusion due to a disturbance of cardiac rhythm should be suspected in patients with known cardiac or vascular disease or in elderly patients who present with episodic loss of consciousness. Prodromal symptoms are typically absent. Repeated Holter monitoring may be necessary to establish the diagnosis; monitoring initiated by the patient (“event monitor”) may be valuable if the disturbances of consciousness are rare. A relationship of attacks to physical activity and the finding of a systolic murmur are suggestive of aortic stenosis.

3. **Brainstem ischemia**—Loss of consciousness is preceded or accompanied by other brainstem signs. Basilar artery migraine and vertebrobasilar vascular disease are discussed elsewhere in this chapter.

4. **Psychogenic nonepileptic seizure (PNES)**—Simulating an epileptic seizure, a PNES may occur due to a conversion disorder or malingering. Many patients also have true seizures or a family history of epilepsy. Although a PNES tends to occur at times of emotional stress, this may also be the case with true seizures.
Clinically, the attacks superficially resemble tonic-clonic seizures, but there may be obvious preparation before a PNES occurs. Moreover, there is usually no tonic phase; instead, there may be an asynchronous thrashing of the limbs, which increases if restraints are imposed and rarely leads to injury. Consciousness may be normal or “lost,” but in the latter context the occurrence of goal-directed behavior or of shouting, swearing, etc., indicates that it is feigned. Postictally, there are no changes in behavior or neurologic findings.

Often, clinical observation is insufficient to discriminate epileptic from nonepileptic seizures. Video electroencephalographic monitoring may be quite helpful: epileptic seizures, especially those involving altered consciousness, commonly involve scalp electroencephalographic signs that coincide with a behavioral spell, whereas a PNES does not. The serum level of prolactin has been found to increase dramatically between 15 and 30 minutes after a tonic-clonic convulsion in most patients, whereas it is unchanged after a PNES. Serum creatine kinase levels also increase after a convulsion but not a PNES.

**Treatment**

**A. General Measures**

For patients with epilepsy, drug treatment is prescribed with the goal of preventing further attacks and is usually continued until there have been no seizures for at least 3 years. Epileptic patients should be advised to avoid situations that could be dangerous or life-threatening if further seizures should occur. Legislation may require clinicians to report to the state authorities any patients with seizures or other episodic disturbances of consciousness; driving cessation for 6 months or as legislated is appropriate following an unprovoked seizure.

1. **Choice of medication**—Drug selection depends on seizure type (Table 24–3). The dose of the selected drug is gradually increased until seizures are controlled or side effects prevent further increases. If seizures continue despite treatment at the maximal tolerated dose, a second drug is added and the dose increased depending on tolerance; the first drug is then gradually withdrawn. In treatment of focal seizures, the success rate is higher with carbamazepine, phenytoin, or valproic acid than with phenobarbital or primidone. Gabapentin, topiramate, lamotrigine, oxcarbazepine, levetiracetam, zonisamide, lacosamide, ezogabine, and tiagabine are newer antiepileptic drugs used to treat focal seizures. Felbamate is also effective for such seizures but, because it may cause aplastic anemia or fulminant hepatic failure, should be used only in selected patients unresponsive to other measures. Rufinamide is currently approved only for seizures in patients with Lennox-Gastaut syndrome, but it may be effective against seizures in a broader range of refractory patients. For generalized or unclassified seizures, valproate is better tolerated than topiramate and more efficacious than lamotrigine and is thus preferred for many patients; however, the teratogenic potential of valproate makes its use undesirable in women of childbearing age. All antiepileptics are potentially teratogenic, although the teratogenicity of the newer antiseizure medications is less clear. Nevertheless, antiepileptic medication must be given to pregnant women with epilepsy to prevent seizures, which can pose serious risk to the fetus from trauma, hypoxia, or other factors. In most patients with seizures of a single type, satisfactory control can be achieved with a single anticonvulsant drug. Treatment with two drugs may further reduce seizure frequency or severity but usually only at the cost of greater toxicity. Treatment with more than two drugs is almost always unhelpful unless the patient is having seizures of different types.

2. **Monitoring**—Monitoring serum drug levels has led to major advances in the management of seizure disorders. Individual differences in drug metabolism cause a given dose of a drug to produce different blood concentrations in different patients, and this will affect the therapeutic response. In general, the dose of an antiepileptic agent is increased depending on the clinical response regardless of the serum drug level. The trough drug level is then measured to provide a reference point for the maximum tolerated dose. Dosing should not be based simply on serum levels because some patients require levels that exceed the therapeutic range (“toxic levels”) but tolerate these without ill effect. Steady-state drug levels in the blood should be measured after treatment is initiated, dosage is changed, or another drug is added to the therapeutic regimen and when seizures are poorly controlled. Dose adjustments are then guided by the laboratory findings. The most common cause of a lower concentration of drug than expected for the prescribed dose is poor patient compliance. Compliance can be improved by limiting to a minimum the number of daily doses. Recurrent seizures or status epilepticus may result if drugs are taken erratically, and in some circumstances noncompliant patients may be better off without any medication.

All anticonvulsant drugs have side effects, and some of these are shown in Table 24–3. In most patients, a complete blood count should be performed at least annually because of the risk of anemia or blood dyscrasias. Treatment with certain drugs may require more frequent monitoring or use of additional screening tests. For example, periodic tests of hepatic function are necessary if valproic acid, carbamazepine, or felbamate is used, and serial blood counts are important with carbamazepine, ethosuximide, or felbamate. Detailed medication-specific recommendations should be sought from a drug reference source before prescribing, since baseline studies are often necessary.

3. **Discontinuance of medication**—Only when adult patients have been seizure-free for 2 years should withdrawal of medication be considered. Unfortunately, there is no way of predicting which patients can be managed successfully without treatment, although seizure recurrence is more likely in patients who initially did not respond to therapy, those with seizures having focal features or of multiple types, and those with continuing electroencephalographic abnormalities. Dose reduction should be gradual (over weeks or months), and drugs should be withdrawn one at a time. If seizures recur, treatment is reinstituted with the previously effective drug regimen.
Table 24-3. Drug treatment for seizures in adults.

1Approved as adjunctive therapy for focal-onset seizures.
2Approved as adjunctive therapy for primary generalized tonic-clonic seizures.
3Approved as initial monotherapy for focal-onset seizures.
4Approved as initial monotherapy for primary generalized tonic-clonic seizures.
5Approved as monotherapy (after conversion from another drug) in focal-onset seizures.
6Not to be used as a first-line drug; when used, blood counts should be performed regularly (every 2–4 weeks). Should be used only in selected patients because of risk of aplastic anemia and hepatic failure. It is advisable to obtain written informed consent before use.
4. Surgical treatment—Patients with seizures refractory to pharmacologic management may be candidates for operative treatment. Surgical resection is most efficacious when there is a single well-defined seizure focus, particularly in the temporal lobe. Among well-chosen patients, up to 70% remain seizure-free after extended follow-up. Using a different approach, a recent trial showed benefits of bilateral deep brain stimulation of the anterior thalamus for medically refractory focal-onset seizures.

5. Vagal nerve stimulation—Treatment by chronic vagal nerve stimulation for adults and adolescents with medically refractory focal seizures is approved in the United States and provides an alternative approach for patients who are not optimal candidates for surgical treatment. The mechanism of therapeutic action is unknown. Adverse effects consist mainly of transient hoarseness during stimulus delivery.

B. Special Circumstances

1. Solitary seizures—In patients who have had only one seizure or a flurry of seizures over a brief period of several hours, investigation as outlined above should exclude an underlying cause requiring specific treatment. An electroencephalogram should also be obtained, preferably within 24 hours after the seizure, because the findings may influence management—especially when focal abnormalities are present. Prophylactic anticonvulsant drug treatment is generally not required unless further attacks occur or investigations reveal some underlying pathology. The risk of seizure recurrence varies in different series between about 30% and 70%. Epilepsy should not be diagnosed on the basis of a solitary seizure. If seizures occur in the context of transient, nonrecurrent systemic disorders such as acute cerebral anoxia, the diagnosis of epilepsy is inaccurate, and long-term prophylactic anticonvulsant drug treatment is unnecessary.

2. Alcohol withdrawal seizures—One or more generalized tonic-clonic seizures may occur within 48 hours or so of withdrawal from alcohol after a period of high or prolonged intake. Patients should be hospitalized for at least 24 hours for observation and to follow the severity of withdrawal symptoms. If the seizures have consistently focal features, the possibility of an associated structural abnormality, often traumatic in origin, must be considered. Head CT scan or MRI should be performed in patients with new onset of generalized seizures and whenever there are focal features. Treatment with anticonvulsant drugs is generally not required for alcohol withdrawal seizures, since they are self-limited. Benzodiazepines (diazepam or lorazepam, dosed as needed to reduce withdrawal symptoms and to avoid oversedation) are effective and safe for preventing further seizures. Status epilepticus may rarely follow alcohol withdrawal and is managed along conventional lines (see below). Further attacks will not occur if the patient abstains from alcohol.

3. Tonic-clonic status epilepticus—Poor compliance with the anticonvulsant drug regimen is the most common cause; others include alcohol withdrawal, intracranial infection or neoplasms, metabolic disorders, and drug overdose. The mortality rate may be as high as 20%, and among survivors the incidence of neurologic and cognitive sequelae may be high. The prognosis relates to the length of time between onset of status epilepticus and the start of effective treatment.

Status epilepticus is a medical emergency. Initial management includes maintenance of the airway and 50% dextrose (25–50 mL) intravenously in case hypoglycemia is responsible. If seizures continue, an intravenous bolus of lorazepam, 4 mg, is given at a rate of 2 mg/min and repeated once after 10 minutes if necessary; alternatively, 10 mg of diazepam is given intravenously over the course of 2 minutes, and again after 10 minutes if necessary. Diazepam can also be given rectally as a gel (0.2 mg/kg). These measures are usually effective in halting seizures for a brief period. Respiratory depression and hypotension may complicate the treatment of status epilepticus and are treated as in other circumstances; this treatment may include intubation and mechanical ventilation and admission to an intensive care unit.

Regardless of the response to lorazepam or diazepam, phenytoin (18–20 mg/kg) is given intravenously at a rate of 50 mg/min; this provides initiation of long-term seizure control. The drug is best injected directly but can also be given in saline; it precipitates, however, if injected into glucose-containing solutions. Because arrhythmias may develop during rapid administration of phenytoin, electrocardiographic monitoring is prudent. Hypotension may complicate phenytoin administration, especially if diazepam has also been given. In many countries, injectable phenytoin has been replaced by fosphenytoin, which is rapidly and completely converted to phenytoin following intravenous administration. No dosing adjustments are necessary because fosphenytoin is expressed in terms of phenytoin equivalents (PE); fosphenytoin is less likely to cause reactions at the infusion site, can be given with all common intravenous solutions, and may be administered at a faster rate (150 mg PE/min). It is also more expensive.

If seizures continue, phenobarbital is then given in a loading dose of 10–20 mg/kg intravenously by slow or intermittent injection (50 mg/min). Respiratory depression and hypotension are especially common with this therapy. Alternatively or additionally, intravenous valproate is used for status epilepticus (loading dose 25–30 mg/kg over 15 min; then 100 mg/h); although valproate has not yet been approved by the FDA for this indication, it has been used with success.

If these measures fail, general anesthesia with ventilatory assistance may be required. Intravenous midazolam may provide control of refractory status epilepticus; the suggested loading dose is 0.2 mg/kg, followed by 0.05–0.2 mg/kg/h. Propofol (1–2 mg/kg as an intravenous bolus, followed by infusion at 2–15 mg/kg/h depending on response) may also be used, as may pentobarbital (15 mg/kg intravenously, followed by 0.5–4 mg/kg/h).

After status epilepticus is controlled, an oral drug program for the long-term management of seizures is started, and investigations into the cause of the disorder are pursued.
4. Nonconvulsive status epilepticus—In some cases, status epilepticus presents not with convulsions, but with a fluctuating abnormal mental status, confusion, impaired responsiveness, and automatism. Electroencephalography is helpful in establishing the diagnosis. The treatment approach outlined above applies to any type of status epilepticus, although intravenous anesthesia is usually not necessary. The prognosis is a reflection of the underlying cause rather than of continuing seizures.

▶ When to Refer
- Behavioral episodes are of uncertain nature.
- Seizures are difficult to control or have focal features.
- There are accompanying neurologic signs.
- There is a progressive neurologic disorder.
- Status epilepticus.

▶ When to Admit
- Status epilepticus.
- For monitoring, when PNES are suspected.
- If surgery is contemplated.

▶ General Considerations
Dysautonomia may occur as a result of central or peripheral pathologic processes. It is manifested by a variety of symptoms that may occur in isolation or in various combinations and relate to abnormalities of blood pressure regulation, thermoregulatory sweating, gastrointestinal function, sphincter control, sexual function, respiration, and ocular function. Syncope, a symptom of dysautonomia, is characterized by a transient loss of consciousness, usually accompanied by hypotension and bradycardia. It may occur in response to emotional stress, postural hypotension, vigorous exercise in a hot environment, obstructed venous return to the heart, acute pain or its anticipation, fluid loss, and a variety of other circumstances.

A. Central Neurologic Causes
Disease at certain sites in the central nervous system, regardless of its nature, may lead to dysautonomic symptoms. Postural hypotension, which is usually the most troublesome and disabling symptom, may result from spinal cord transection and other myopathies (eg, due to tumor or syringomyelia) above the T6 level or from brainstem lesions such as syringobulbia and posterior fossa tumors. Sphincter or sexual disturbances may result from cord lesions below T6. Certain primary degenerative disorders are responsible for dysautonomia occurring in isolation (pure autonomic failure) or in association with more widespread abnormalities (multisystem atrophy or Shy-Drager syndrome) that may include parkinsonian, pyramidal symptoms, and cerebellar deficits.

B. Peripheral Neurologic Causes
A pure autonomic neuropathy may occur acutely or subacutely after a viral infection or as a paraneoplastic disorder related usually to small cell lung cancer, particularly in association with certain antibodies, such as anti-Hu or those directed at neuronal nicotinic acetylcholine receptors. Typically, presenting symptoms include postural hypotension, impaired thermoregulatory sweating, xerostomia or xerophthalmia, abnormal gastrointestinal motility, dilated pupils, or acute urinary retention. Dysautonomia is often conspicuous in patients with Guillain-Barré syndrome, manifesting with marked hypotension or hypertension or cardiac arrhythmias that may have a fatal outcome. It may also occur with diabetic, uremic, amyloidotic, and various other metabolic or toxic neuropathies; in association with leprosy or Chagas disease; and as a feature of certain hereditary neuropathies with autosomal dominant or recessive inheritance or an X-linked pattern. Autonomic symptoms are prominent in the crises of hepatic porphyria. Patients with botulism or the Lambert-Eaton myasthenic syndrome may have constipation, urinary retention, and a sicca syndrome as a result of impaired cholinergic function.

▶ Clinical Findings
A. Symptoms and Signs
Dysautonomic symptoms include syncope, postural hypotension, paroxysmal hypertension, persistent tachycardia.
without other cause, facial flushing, hypohidrosis or hyperhidrosis, vomiting, constipation, diarrhea, dysphagia, abdominal distention, disturbances of micturition or defecation, erectile dysfunction, apneic episodes, and declining night vision. In syncope, prodromal malaise, nausea, headache, diaphoresis, pallor, visual disturbance, loss of postural tone, and a sense of weakness and impending loss of consciousness are followed by actual loss of consciousness. Although the patient is usually flaccid, some motor activity is not uncommon, and urinary (and rarely fecal) incontinence may also occur, thereby simulating a seizure. Recovery is rapid once the patient becomes recumbent, but headache, nausea, and fatigue are common postictally.

B. Evaluation of the Patient

Clinical evaluation is important to exclude reversible, nonneurologic causes of symptoms. Postural hypotension and syncope, for example, may relate to a reduced cardiac output (eg, from aortic stenosis or cardiomyopathy), paroxysmal cardiac dysrhythmias, volume depletion, various medications, and endocrine and metabolic disorders such as Addison disease, hypothyroidism or hyperthyroidism, pheochromocytoma, and carcinoid syndrome. Testing of autonomic function helps establish the diagnosis of dysautonomia, to exclude other causes of symptoms, to assess the severity of involvement, and to guide prognostication. Such testing includes evaluating the cardiovascular response to the Valsalva maneuver, startle, mental stress, postural change, and deep respiration, and the sudomotor (sweating) responses to warming or a deep inspiratory gasp. Tilt-table testing may reproduce syncopal or presyncopal symptoms. Pharmacologic studies to evaluate the pupillary responses, radiologic studies of the bladder or gastrointestinal tract, uroflowmetry and urethral pressure profiles, and recording of nocturnal penile tumescence may also be necessary in selected cases. Further investigation depends on the presence of other associated neurologic abnormalities. In patients with a peripheral cause, work-up for peripheral neuropathy may be required as discussed below and should include testing for ganglionic acetylcholine receptor antibody. For those with evidence of a central lesion, imaging studies will exclude a treatable structural cause.

Treatment

The most disabling symptom of dysautonomia is usually postural hypotension and syncope. Abrupt postural change, prolonged recumbency, and other precipitants should be avoided. Medications associated with postural hypotension should be discontinued or reduced in dose. Treatment may include wearing waist-high elastic hosiery, salt supplementation, sleeping in a semierect position (which minimizes the natriuresis and diuresis that occur during recumbency), and fludrocortisone (0.1–0.2 mg daily). Vasoconstrictor agents may be helpful and include midodrine (2.5–10 mg three times daily) and ephedrine (15–30 mg three times daily). Other agents that have been used occasionally or experimentally are dihydroergotamine, yohimbine, pyridostigmine, and clonidine; refractory cases may respond to erythropoietin (epoetin alfa) or desmopressin. Patients must be monitored for recumbent hypotension. Postprandial hypotension is helped by caffeine. There is no satisfactory treatment for disturbances of sweating, but an air-conditioned environment is helpful in avoiding extreme swings in body temperature.

When to Refer

- When the diagnosis is uncertain.
- When symptoms persist despite conventional treatment.

SENSORY DISTURBANCES

Patients may complain of either lost or abnormal sensations. The term “numbness” is often used by patients to denote loss of feeling, but the word also has other meanings and the patient’s intention must be clarified. Abnormal spontaneous sensations are generally called paresthesias, and unpleasant or painful sensations produced by a stimulus that is usually painless are called dysesthesias.

Sensory symptoms may be due to disease located anywhere along the peripheral or central sensory pathways. The character, site, mode of onset, spread, and temporal profile of sensory symptoms must be established and any precipitating or relieving factors identified. These features—and the presence of any associated symptoms—help identify the origin of sensory disturbances, as do the physical signs as well. Sensory symptoms or signs may conform to the territory of individual peripheral nerves or nerve roots. Involvement of one side of the body—or of one limb in its entirety—suggests a central lesion. Distal involvement of all four extremities suggests polyneuropathy, a cervical cord or brainstem lesion, or—when symptoms are transient—a metabolic disturbance such as hyperventilation syndrome. Short-lived sensory complaints may be indicative of sensory seizures or cerebral ischemic phenomena as well as metabolic disturbances. In patients with cord lesions, there may be a transverse sensory level. “Dissociated sensory loss” is characterized by loss of some sensory modalities with preservation of others. Such findings may be encountered in patients with either peripheral or central disease and must therefore be interpreted in the clinical context in which they are found.

The absence of sensory signs in patients with sensory symptoms does not mean that symptoms have a nonorganic basis. Symptoms are often troublesome before signs of sensory dysfunction have had time to develop.
**WEAKNESS & PARALYSIS**

Loss of muscle power may result from central disease involving the upper or lower motor neurons; from peripheral disease involving the roots, plexus, or peripheral nerves; from disorders of neuromuscular transmission; or from primary disorders of muscle. The clinical findings help localize the lesion and thus reduce the number of diagnostic possibilities.

Weakness due to upper motor neuron lesions is characterized by selective involvement of certain muscle groups and is associated with spasticity, increased tendon reflexes, and extensor plantar responses. The site of upper motor neuron (pyramidal) involvement may be indicated by the presence of other clinical signs or by the distribution of the motor deficit. Lower motor neuron lesions lead to muscle wasting as well as weakness, with flaccidity and loss of tendon reflexes, but no change in the plantar responses unless the neurons subserving them are directly involved. Fasciculations may be evident over affected muscles. In distinguishing between a root, plexus, or peripheral nerve lesion, the distribution of the motor deficit and of any sensory changes is of particular importance. In patients with disturbances of neuromuscular transmission, weakness is patchy in distribution, often fluctuates over short periods of time, and is not associated with sensory changes. In myopathic disorders, weakness is usually most marked proximally in the limbs, is not associated with sensory loss or sphincter disturbance, and is not accompanied by muscle wasting or loss of tendon reflexes—at least not until an advanced stage.

**TRANSIENT ISCHEMIC ATTACKS**

**Essentials of Diagnosis**

- Focal neurologic deficit of acute onset.
- Clinical deficit resolves completely within 24 hours.
- Risk factors for vascular disease often present.

**General Considerations**

Transient ischemic attacks are characterized by focal ischemic cerebral neurologic deficits that last for <24 hours (usually <1–2 hours). About 30% of patients with stroke have a history of transient ischemic attacks, and proper treatment of the attacks is an important means of prevention. The incidence of stroke does not relate to either the number or the duration of individual attacks but is increased in patients with hypertension or diabetes mellitus. The risk of stroke is highest in the month after a transient ischemic attack (particularly in the first 48 hours) and progressively declines thereafter.

**Etiology**

An important cause of transient cerebral ischemia is embolization. In many patients with these attacks, a source is readily apparent in the heart or a major extracranial artery to the head, and emboli sometimes are visible in the retinal arteries. Moreover, an embolic phenomenon explains why separate attacks may affect different parts of the territory supplied by the same major vessel. Cardiac causes of embolic ischemic attacks include atrial fibrillation, rheumatic heart disease, mitral valve disease, infective endocarditis, atrial myxoma, and mural thrombi complicating myocardial infarction. Atrial septal defects and patent foramen ovale may permit emboli from the veins to reach the brain (“paradoxical emboli”). An ulcerated plaque on a major artery to the brain may serve as a source of emboli. In the anterior circulation, atherosclerotic changes occur most commonly in the region of the carotid bifurcation extracranially, and these changes may cause a bruit. In some patients with transient ischemic attacks or strokes, an acute or recent hemorrhage is found to have occurred into this atherosclerotic plaque, and this finding may have pathologic significance. Patients with AIDS have an increased risk of developing transient ischemic deficits or strokes.

Less common abnormalities of blood vessels that may cause transient ischemic attacks include fibromuscular dysplasia, which affects particularly the cervical internal carotid artery; atherosclerosis of the aortic arch; inflammatory arterial disorders such as giant cell arteritis, systemic lupus erythematosus, polyarteritis, and granulomatous angiitis; and meningovascular syphilis. Hypotension may cause a reduction of cerebral blood flow if a major extracranial artery to the brain is markedly stenosed, but this is a rare cause of transient ischemic attack.

Hematologic causes of ischemic attacks include polycythemia, sickle cell disease, and hyperviscosity syndromes. Severe anemia may also lead to transient focal neurologic deficits in patients with preexisting cerebral arterial disease.

The subclavian steal syndrome may lead to transient vertebrobasilar ischemia. Symptoms develop when there is localized stenosis or occlusion of one subclavian artery proximal to the source of the vertebral artery, so that blood is “stolen” from this artery. A bruit in the supraclavicular fossa, unequal radial pulses, and a difference of 20 mm Hg or more between the systolic blood pressures in the arms should suggest the diagnosis in patients with vertebrobasilar transient ischemic attacks.

**Clinical Findings**

**A. Symptoms and Signs**

The symptoms of transient ischemic attacks vary markedly among patients; however, the symptoms in a given individual tend to be constant in type. Onset is abrupt and without warning, and recovery usually occurs rapidly, often within a few minutes. The specific symptoms depend on the arterial distribution affected, as outlined in the subsequent section on stroke.

The natural history of attacks is variable. Some patients will have a major stroke after only a few attacks, whereas others may have frequent attacks for weeks or months without having a stroke. The risk of stroke is high in the...
first 3 months after an attack, particularly in the first month and especially within the first 48 hours. Attacks may occur intermittently over a long period of time, or they may stop spontaneously. In general, carotid ischemic attacks are more liable than vertebrobasilar ischemic attacks to be followed by stroke. The stroke risk is greater in patients older than 60 years, in diabetics, or after transient ischemic attacks that last longer than 10 minutes and with symptoms or signs of weakness, speech impairment, or gait disturbance.

B. Imaging

CT or MRI scan is indicated within 24 hours of symptom onset, in part to exclude the possibility of a small cerebral hemorrhage or a cerebral tumor masquerading as a transient ischemic attack; MRI with diffusion-weighted sequences is particularly sensitive for revealing acute or subacute infarction. Noninvasive imaging of the cerebral vasculature should also be performed. Carotid duplex ultrasonography is useful for detecting significant stenosis of the internal carotid artery, and MR or CT angiography permits broader visualization of cervical and intracranial vasculature. When noninvasive studies fail to reveal an etiology for transient ischemic attacks, conventional cerebral arteriography may be indicated. This technique is the gold standard for investigating the integrity of the cervical and cerebral vasculature, and allows for angioplasty or other interventions, if necessary.

C. Laboratory and Other Studies

Clinical and laboratory evaluation must include assessment for hypertension, heart disease, hematologic disorders, diabetes mellitus, hyperlipidemia, and peripheral vascular disease. It should include complete blood count, fasting blood glucose and serum cholesterol and homocysteine determinations, serologic tests for syphilis, and an ECG and chest radiograph. Echocardiography with bubble contrast is performed if a cardiac source is likely, and blood cultures are obtained if endocarditis is suspected. Holter monitoring is indicated if a transient, paroxysmal disturbance of cardiac rhythm is suspected.

Differential Diagnosis

Focal seizures usually cause abnormal motor or sensory phenomena such as clonic limb movements, paresthesias, or tingling, rather than weakness or loss of feeling. Symptoms generally spread (“march”) up the limb and may lead to a generalized tonic-clonic seizure.

Classic migraine is easily recognized by the visual premonitory symptoms, followed by nausea, headache, and photophobia, but less typical cases may be hard to distinguish. The patient’s age and medical history (including family history) may be helpful in this regard. Patients with migraine commonly have a history of episodes since adolescence and report that other family members have a similar disorder.

Focal neurologic deficits may occur during periods of hypoglycemia in diabetic patients receiving insulin or oral hypoglycemic agent therapy.

Treatment

Hospitalization should be considered for patients seen within 72 hours of the attack, when they are at increased risk for early recurrence. One commonly used method to assess recurrence risk is the ABCD² score; points are assigned for each of the following criteria: age 60 years or older (1 point), blood pressure ≥140/90 mm Hg (1 point), clinical symptoms of focal weakness (2 points) or speech impairment without weakness (1 point), duration ≥60 minutes (2 points) or 10–59 minutes (1 point), or diabetes mellitus (1 point). An ABCD² score of 3 or more points has been suggested as a threshold for hospital admission. Admission is also advisable for patients with crescendo attacks, symptomatic carotid stenosis, or known cardiac source of emboli or hypercoagulable state; such hospitalization facilitates early intervention for any recurrence and rapid institution of secondary prevention measures. When arteriography reveals a surgically accessible high-grade stenosis (70–99% in luminal diameter) on the side appropriate to carotid ischemic attacks and there is relatively little atherosclerosis elsewhere in the cerebrovascular system, operative treatment (carotid endarterectomy) or endovascular intervention reduces the risk of ipsilateral carotid stroke, especially when transient ischemic attacks are of recent onset (<1 month). Some evidence suggests that trans luminal angioplasty and stenting is inferior to aggressive medical management alone. There is a more moderate benefit for patients with 50–69% stenosis, and surgery is not indicated for mild stenosis (<50%); its benefits are unclear with severe stenosis plus diffuse intracranial atherosclerotic disease. In patients with carotid ischemic attacks who are poor operative candidates (and thus have not undergone arteriography) or who are found to have extensive vascular disease, medical treatment should be instituted. Similarly, patients with vertebrobasilar ischemic attacks are treated medically and are not subjected to arteriography unless there is clinical evidence of stenosis or occlusion in the carotid or subclavian arteries.

Medical treatment is aimed at preventing further attacks and stroke. Treat diabetes mellitus; hematologic disorders; and hypertension, preferably with an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker. Consider starting a statin medication regardless of the current low-density lipoprotein level; in addition to reducing stroke risk, antecedent statin use may improve the outcome if an ischemic stroke does occur. Cigarette smoking should be stopped, and cardiac sources of embolization should be treated appropriately. Weight reduction and regular physical activity should be encouraged when appropriate.

A. Embolization from the Heart

Cardioembolism, especially in the setting of atrial fibrillation, is an indication for anticoagulation as a preventive treatment for stroke. If anticoagulants are indicated for the treatment of embolism from the heart, they should be started immediately, provided that the area of cerebral infarct is small and there is no contraindication to their use. There is no advantage in delay, and the common fear of causing hemorrhage into a previously infarced area is
distinctive neurologic signs reflect the region of the brain involved.

dosage, and no requirement for monitoring. Compared with warfarin, the direct thrombin inhibitor dabigatran (150 mg twice daily) offers improved reduction of stroke risk, similar or lower risk of hemorrhage, easier dosing, and no requirement for monitoring.

**B. Noncardioembolic Attacks**

Treatment with low-dose aspirin (81 mg daily orally) significantly reduces the frequency of transient ischemic attacks and the incidence of stroke. For patients who continue to experience transient ischemic attacks on low-dose aspirin, higher doses of aspirin show no additional benefit. However, low-dose aspirin combined with sustained-release dipyridamole (200 mg twice daily orally) has been shown to be more effective in preventing stroke than aspirin alone. Clopidogrel (75 mg daily orally) alone is marginally more efficacious than aspirin alone; combining clopidogrel with aspirin is not clearly better than clopidogrel alone but does increase the risk of bleeding complications. Cilostazol, another antiplatelet medication, appears to offer similar efficacy at stroke prevention as aspirin, and possibly less risk of hemorrhage. Antiplatelet drugs are not recommended, as they offer no benefit over antiplatelet therapy, and the risk of serious hemorrhagic adverse effects is greater.

**When to Refer**

All patients should be referred for urgent investigation and treatment to prevent stroke.

**When to Admit**

If seen within 72 hours of a transient ischemic attack, patients should be considered for admission when they have an ABCD² score of 3 points or more, when outpatient evaluation is impractical, or when there are crescendo attacks or other concern for early recurrence or stroke.

---

**StROKE**

**ESSENTIALS OF DIAGNOSIS**

- Sudden onset of characteristic neurologic deficit.
- Patient often has history of hypertension, diabetes mellitus, valvular heart disease, or atherosclerosis.
- Distinctive neurologic signs reflect the region of the brain involved.

**General Considerations**

In the United States, stroke remains the third leading cause of death, despite a general decline in the incidence of stroke in the last 30 years. The precise reasons for this decline are uncertain, but increased awareness of risk factors (hypertension, diabetes mellitus, hyperlipidemia, cigarette smoking, cardiac disease, AIDS, recreational drug abuse, heavy alcohol consumption, family history of stroke) and improved prophylactic measures and surveillance of those at increased risk have been contributory. Elevation of the blood homocysteine level is also a risk factor for stroke, but it is unclear whether this risk is reduced by treatment to lower the level. A previous stroke makes individual patients more susceptible to additional strokes.

For years, strokes have been subdivided pathologically into infarcts (thrombotic or embolic) and hemorrhages, and clinical criteria for distinguishing between these possibilities have been emphasized. However, it is often difficult to determine on clinical grounds the pathologic basis for stroke (Table 24–4).

### 1. Lacunar Infarction

Lacunar infarcts are small lesions (usually <5 mm in diameter) that occur in the distribution of short penetrating arteries in the basal ganglia, pons, cerebellum, internal capsule, thalamus and, less commonly, the deep cerebral white matter. Lacunar infarcts are associated with poorly controlled hypertension or diabetes and have been found in several clinical syndromes, including contralateral pure motor or pure sensory deficit, ipsilateral ataxia with cranial paresis, and dysarthria with clumsiness of the hand. The neurologic deficit may progress over 24–36 hours before stabilizing.

</tbody>
</table>

AVMs, arteriovenous malformations; CTA, computed tomography angiography; MRA, magnetic resonance angiography.
Lacunar infarcts are sometimes visible on CT scans as small, punched-out, hypodense areas, but in other patients no abnormality is seen. In some instances, patients with a clinical syndrome suggestive of lacunar infarction are found on CT scanning to have a severe hemispheric infarct. Diffusion-weighted MRI is sensitive to acute lesions, which later evolve into areas of T2 hyperintensity and eventually into small, punched-out, cerebrospinal fluid–filled spaces.

Early mortality and risk of stroke recurrence is higher for patients with nonlacunar than lacunar infarcts. The prognosis for recovery from the deficit produced by a lacunar infarct is usually good, with partial or complete resolution occurring over the following 4–6 weeks in many instances.

2. Cerebral Infarction

Thrombotic or embolic occlusion of a major vessel leads to cerebral infarction. Causes include the disorders predisposing to transient ischemic attacks (see above) and atherosclerosis of cerebral arteries. The resulting deficit depends on the particular vessel involved and the extent of any collateral circulation. Cerebral ischemia leads to release of excitatory and other neuropeptidases that may augment calcium flux into neurons, thereby leading to cell death and increasing the neurologic deficit.

Clinical Findings

A. Symptoms and Signs

Onset is usually abrupt, and there may then be very little progression except that due to brain swelling. Clinical evaluation should always include examination of the heart and auscultation over the subclavian and carotid vessels to determine whether there are any bruits.

1. Obstruction of carotid circulation—Oclusion of the ophthalmic artery is probably symptomless in most cases because of the rich orbital collaterals, but its transient embolic obstruction can lead to amaurosis fugax—sudden and brief loss of vision in one eye.

Oclusion of the anterior cerebral artery distal to its junction with the anterior communicating artery causes weakness and cortical sensory loss in the contralateral leg and sometimes mild weakness of the arm, especially proximally. There may be a contralateral grasp reflex, paratonic rigidity, and abulia (lack of initiative) or frank confusion. Urinary incontinence is not uncommon, particularly if behavioral disturbances are conspicuous. Bilateral anterior cerebral infarction is especially likely to cause marked behavioral changes and memory disturbances. Unilateral anterior cerebral artery occlusion proximal to the junction with the anterior communicating artery is generally well tolerated because of the collateral supply from the other side.

Middle cerebral artery occlusion leads to contralateral hemiplegia, hemisensory loss, and homonymous hemianopia (ie, bilaterally symmetric loss of vision in half of the visual fields), with the eyes deviated to the side of the lesion. If the dominant hemisphere is involved, global aphasia is also present. It may be impossible to distinguish this clinically from occlusion of the internal carotid artery. With occlusion of either of these arteries, there may also be considerable swelling of the hemisphere, leading to drowsiness, stupor, and coma in extreme cases. Occlusions of different branches of the middle cerebral artery cause more limited findings. For example, involvement of the anterior main division leads to a predominantly expressive dysphasia and to contralateral paralysis and loss of sensations in the arm, the face and, to a lesser extent, the leg. Posterior branch occlusion produces a receptive (Wernicke) aphasia and a homonymous visual field defect. With involvement of the nondominant hemisphere, speech and comprehension are preserved, but there may be a left hemispatial neglect syndrome or constructional and visuospatial deficits.

2. Obstruction of vertebrobasilar circulation—Oclusion of the posterior cerebral artery may lead to a thalamic syndrome in which contralateral hemisensory disturbance occurs, followed by the development of spontaneous pain and hyperpathia. There is often a macular-sparing homonymous hemianopia and sometimes a mild, usually temporary, hemiparesis. Depending on the site of the lesion and the collateral circulation, the severity of these deficits varies and other deficits may also occur, including involuntary movements and alexia. Oclusion of the main artery beyond the origin of its penetrating branches may lead solely to a macular-sparing hemianopia.

Vertebral artery occlusion distally, below the origin of the anterior spinal and posterior inferior cerebellar arteries, may be clinically silent because the circulation is maintained by the other vertebral artery. If the remaining vertebral artery is congenitally small or severely atherosclerotic, however, a deficit similar to that of basilar artery occlusion is seen unless there is good collateral circulation from the anterior circulation through the circle of Willis. When the small paramedian arteries arising from the vertebral artery are occluded, contralateral hemiplegia and sensory deficit occur in association with an ipsilateral cranial nerve palsy at the level of the lesion. An obstruction of the posterior inferior cerebellar artery or an obstruction of the vertebral artery just before it branches to this vessel leads to ipsilateral spinthalamic sensory loss involving the face, ninth and tenth cranial nerve lesions, limb ataxia and numbness, and Horner syndrome, combined with contralateral spinthalamic sensory loss involving the limbs.

Oclusion of both vertebral arteries or the basilar artery leads to coma with pinpoint pupils, flaccid quadriplegia and sensory loss, and variable cranial nerve abnormalities. With partial basilar artery occlusion, there may be diplopia, visual loss, vertigo, dystartria, ataxia, weakness or sensory disturbances in some or all of the limbs, and discrete cranial nerve palsies. In patients with hemiplegia of pontine origin, the eyes are often deviated to the paralyzed side, whereas in patients with a hemispheric lesion, the eyes commonly deviate from the hemiplegic side.

Oclusion of any of the major cerebellar arteries produces vertigo, nausea, vomiting, nystagmus, ipsilateral limb ataxia, and contralateral spinthalamic sensory loss in the
Prophylactic measures were considered earlier in discussing transient ischemic attacks. The management of acute stroke should be in a stroke care unit, when feasible. Intravenous thrombolytic therapy with recombinant tissue plasminogen activator (rtPA; 0.9 mg/kg to a maximum of 90 mg, with 10% given as a bolus over 1 minute and the remainder over 1 hour) is effective in reducing the neurologic deficit in selected patients without CT evidence of intracranial hemorrhage when administered as soon as possible, but not more than 4.5 hours after the onset of ischemic symptoms. Treatment within 3 hours has the strongest evidence for benefit (and has FDA approval), but more recent data suggest that extending the treatment window to 4.5 hours still results in reduced disability at 90 days. Based on those data and the recommendations of professional societies, many emergency hospitals have adopted this longer treatment window. Recent hemorrhage, increased risk of hemorrhage (eg, treatment with anticoagulants), arterial puncture at a noncompressible site, and systolic pressure >185 mm Hg or diastolic pressure >110 mm Hg are among the contraindications to this treatment. In selected patients with thrombotic stroke, percutaneous procedures, including endovascular intra-arterial rtPA administration or mechanical removal of an embolus or clot from an occluded cerebral artery using an intra-arterial mechanical thrombolytic device, are also effective relative to non-thrombolytic medical treatment, despite an increased risk of intracranial hemorrhage; it is not clear how these invasive approaches compare to intravenous thrombolytic therapy.

Early management of a completed stroke otherwise requires general supportive measures. During the acute stage, there may be marked brain swelling and edema, with symptoms and signs of increasing intracranial pressure, an increasing neurologic deficit, or herniation syndrome. Elevated intracranial pressure is managed by head elevation and osmotic agents such as mannitol. Maintenance of an adequate cerebral perfusion pressure helps prevent further ischemia. Decompressive hemicraniectomy for malignant middle cerebral artery infarctions may reduce mortality and improve functional outcome in some instances. Attempts to lower the blood pressure of hypertensive patients during the acute phase (ie, within 2 weeks) of a stroke should generally be avoided, as there is loss of cerebral autoregulation, and lowering the blood pressure may further compromise ischemic areas. However, if the systolic pressure exceeds 220 mm Hg, it can be lowered using intravenous labetalol or nicardipine with continuous monitoring to 170–200 mm Hg and then, after 2 weeks, it can be reduced further to <140/90 mm Hg.

In patients not eligible for thrombolytic therapy, and in whom hemorrhage has been excluded by CT, the immediate administration of aspirin 325 mg orally daily is indicated. Anticoagulant drugs should be started in the setting of atrial fibrillation or other source of cardioembolism. Treatment is with warfarin (target INR 2.0–3.0) or dabigatran (150 mg twice daily). If the CT scan shows no evidence of hemorrhage and the cerebrospinal fluid is clear, anticoagulant treatment may be started without delay.

Physical therapy has an important role in the management of patients with impaired motor function. Passive movements at an early stage will help prevent contractures.

3. Coma—Infarction in either the carotid or vertebrobasilar territory may lead to loss of consciousness. For example, an infarct involving one cerebral hemisphere may lead to such swelling that the function of the other hemisphere or the rostral brainstem is disturbed and coma results. Similarly, coma occurs with bilateral brainstem infarction when this involves the reticular formation, and it occurs with brainstem compression after cerebellar infarction.

### B. Imaging

A CT scan of the head (without contrast) should be performed immediately, before the administration of aspirin or other antithrombotic agents, to exclude cerebral hemorrhage. CT is relatively insensitive to acute ischemic stroke, and subsequent MRI with diffusion-weighted sequences should be performed to define the distribution and extent of infarction as well as to exclude tumor or other differential considerations. Perfusion-weighted MRI sequences can be useful for outlining any additional areas at risk for infarction, thus guiding treatment decisions; specific guidelines are still being determined. Imaging of the cerebral vasculature is indicated as part of a search to identify the source of the stroke.

### C. Laboratory and Other Studies

Investigations should include a complete blood count, erythrocyte sedimentation rate, blood glucose determination, and serologic tests for syphilis. Screening for antiphospholipid antibodies (lupus anticoagulants and anticardiolipin antibodies); the factor V Leiden mutation; abnormalities of protein C, protein S, or antithrombin; or a prothrombin gene mutation is indicated if a hypercoagulable disorder is suspected (eg, a young patient without apparent risk factors for stroke). Similarly, elevated serum cholesterol and lipids and serum homocysteine may indicate an increased risk of thrombotic stroke. Electrocardiography or continuous cardiac monitoring for at least 24 hours will help exclude a recent myocardial infarction or a cardiac arrhythmia that might be serving as a source of embolization. Blood cultures should be performed if endocarditis is suspected, echocardiography (bubble contrast study) if heart disease—especially valvular disease, left-to-right shunting, or cardiac thrombus—is a concern, and Holter monitoring if paroxysmal cardiac arrhythmia requires exclusion. Examination of the cerebrospinal fluid is not always necessary but may be helpful if cerebral vasculitis or another inflammatory or infectious cause of stroke is suspected, but it should be delayed until after CT or MRI to exclude any risk for herniation due to mass effect.

#### Treatment

Physical therapy has an important role in the management of patients with impaired motor function. Passive movements at an early stage will help prevent contractures.
As cooperation increases and some recovery begins, active movements will improve strength and coordination. In all cases, early mobilization and active rehabilitation are important. Occupational therapy may improve morale and motor skills, while speech therapy may be beneficial in patients with expressive dysphasia or dysarthria. Because of the risk for dysphagia following stroke, access to food and drink is typically restricted until an appropriate swallowing evaluation. When there is a severe and persistent motor deficit, a device such as a leg brace, toe spring, frame, or cane may help the patient move about, and the provision of other aids to daily living may improve the quality of life.

**Prognosis**

The prognosis for survival after cerebral infarction is better than after cerebral or subarachnoid hemorrhage. The only proved effective therapy for acute stroke requires initiation within 3–4.5 hours after stroke onset, and the prognosis therefore depends on the time that elapses before arrival at the hospital. Patients receiving such treatment with rtPA are at least 30% more likely to have minimal or no disability at 3 months than those not treated by this means. Loss of consciousness after a cerebral infarct implies a poorer prognosis than otherwise. The extent of the infarct governs the potential for rehabilitation. Patients who have had a cerebral infarct are at risk for additional strokes and for myocardial infarcts. Statin therapy to lower serum lipid levels may reduce this risk. Antiplatelet therapy reduces the recurrence rate by 30% among patients without a cardiac cause for the stroke who are not candidates for carotid endarterectomy. Nevertheless, the cumulative risk of recurrence of noncardioembolic stroke is still 3–7% annually. Patients with massive strokes from which meaningful recovery is unlikely should receive palliative care (see Chapter 5).

**When to Refer**

All patients should be referred.

**When to Admit**

All patients should be hospitalized, preferably in a stroke care unit.

---

3. Intracerebral Hemorrhage

Spontaneous, nontraumatic intracerebral hemorrhage in patients with no angiographic evidence of an associated vascular anomaly (eg, aneurysm or angioma) is usually due to hypertension. The pathologic basis for hemorrhage is probably the presence of microaneurysms that develop on perforating vessels in hypertensive patients. Hypertensive intracerebral hemorrhage occurs most frequently in the basal ganglia and less commonly in the pons, thalamus, cerebellum, and cerebral white matter. Hemorrhage may extend into the ventricular system or subarachnoid space, and signs of meningeal irritation are then found. Hemorrhages usually occur suddenly and without warning, often during activity. In the elderly, cerebral amyloid angiopathy is another important and frequent cause of hemorrhage, which is usually lobar in distribution, sometimes recurrent, and associated with a better prognosis than hypertensive hemorrhage.

Other causes of nontraumatic intracerebral hemorrhage include hematologic and bleeding disorders (eg, leukemia, thrombocytopenia, hemophilia, or disseminated intravascular coagulation), anticoagulant therapy, liver disease, high alcohol intake, and primary or secondary brain tumors. There is also an association with advancing age and male sex. Bleeding is primarily into the subarachnoid space when it occurs from an intracranial aneurysm or arteriovenous malformation (see below), but it may be partly intraparenchymal as well. In some cases, no specific cause for cerebral hemorrhage can be identified.

**Clinical Findings**

**A. Symptoms and Signs**

With hemorrhage into the cerebral hemisphere, consciousness is initially lost or impaired in about one-half of patients. Vomiting occurs very frequently at the onset of bleeding, and headache is sometimes present. Focal symptoms and signs then develop, depending on the site of the hemorrhage. With hypertensive hemorrhage, there is generally a rapidly evolving neurologic deficit with hemiplegia or hemiparesis. A hemisensory disturbance is also present with more deeply placed lesions. With lesions of the putamen, loss of conjugate lateral gaze may be conspicuous. With thalamic hemorrhage, there may be a loss of upward gaze, downward or skew deviation of the eyes, lateral gaze palsies, and pupillary inequalities.
Cerebellar hemorrhage may present with sudden onset of nausea and vomiting, dysequilibrium, headache, and loss of consciousness that may terminate fatally within 48 hours. Less commonly, the onset is gradual and the course episodic or slowly progressive—clinical features suggesting an expanding cerebellar lesion. In yet other cases, however, the onset and course are intermediate, and examination shows lateral conjugate gaze palsies to the side of the lesion; small reactive pupils; contralateral hemiplegia; peripheral facial weakness; ataxia of gait, limbs, or trunk; periodic respiration; or some combination of these findings.

B. Imaging

CT scanning (without contrast) is important not only in confirming that hemorrhage has occurred but also in determining the size and site of the hematoma. It is superior to MRI for detecting intracranial hemorrhage of < 48 hours duration. If the patient’s condition permits further intervention, CT angiography, MR angiography, or cerebral angiography may be undertaken thereafter to determine whether an aneurysm or arteriovenous malformation is present (see below). Follow-up imaging during the hospitalization may reveal hematoma expansion, a predictor of poor outcome.

C. Laboratory and Other Studies

A complete blood count, platelet count, bleeding time, prothrombin and partial thromboplastin times, and liver and kidney function tests may reveal a predisposing cause for the hemorrhage. Lumbar puncture is contraindicated because it may precipitate a herniation syndrome in patients with a large hematoma, and CT scanning is superior in detecting intracerebral hemorrhage.

Treatment

Neurologic management is generally conservative and supportive, regardless of whether the patient has a profound deficit with associated brainstem compression, in which case the prognosis is grim, or a more localized deficit not causing increased intracranial pressure or brainstem involvement. Such therapy may include ventilatory support, blood pressure regulation, seizure prophylaxis, control of fever, osmotherapy, and nutritional supplementation. Intracranial pressure may require monitoring. Ventricular drainage may be required in patients with intraventricular hemorrhage and acute hydrocephalus. Decompression may be helpful when a superficial hematoma in cerebral white matter is exerting a mass effect and causing incipient herniation. In patients with cerebellar hemorrhage, prompt surgical evacuation of the hematoma is appropriate, because spontaneous unpredictable deterioration may otherwise lead to a fatal outcome and because operative treatment may lead to complete resolution of the clinical deficit. The treatment of underlying structural lesions or bleeding disorders depends on their nature. Hemostatic therapy with recombinant activated factor VII has not improved survival or functional outcome. There is no specific treatment for cerebral amyloid angiopathy.

When to Refer

All patients should be referred.

When to Admit

All patients should be hospitalized.

Ruchey S et al. Does this patient have a hemorrhagic stroke?: clinical findings distinguishing hemorrhagic stroke from ischemic stroke. JAMA. 2010 Jun 9;303(22):2280–6. [PMID: 20530782]

4. Spontaneous Subarachnoid Hemorrhage

ESSENTIALS OF DIAGNOSIS

- Sudden severe headache.
- Signs of meningeal irritation usually present.
- Obtundation is common.
- Focal deficits frequently absent.

General Considerations

Between 5% and 10% of strokes are due to subarachnoid hemorrhage. Trauma is the most common cause of subarachnoid hemorrhage, the prognosis of which depends on the severity of the head injury. Spontaneous (nontraumatic) subarachnoid hemorrhage frequently results from the rupture of an arterial saccular (“berry”) aneurysm or from an arteriovenous malformation. Occasional patients with aneurysms have headaches, sometimes accompanied by nausea and neck stiffness, a few hours or days before massive subarachnoid hemorrhage occurs. This has been attributed to “warning leaks” of a small amount of blood from the aneurysm.

Clinical Findings

A. Symptoms and Signs

Subarachnoid hemorrhage has a characteristic clinical picture. Its onset is with sudden headache of a severity never experienced previously by the patient. This may be followed by nausea and vomiting and by a loss or impairment of consciousness that can either be transient or progress inexorably to deepening coma and death. If consciousness is regained, the patient is often confused and irritable and may show other symptoms of an altered mental status. Neurologic examination generally reveals nuchal rigidity and other signs of meningeal irritation, except in deeply comatose patients.
Aneurysms may cause a focal neurologic deficit by compressing adjacent structures. However, most are asymptomatic or produce only nonspecific symptoms until they rupture, at which time subarachnoid hemorrhage results. A higher risk of subarachnoid hemorrhage is associated with older age, female sex, “nonwhite” ethnicity, hypertension, tobacco smoking, high alcohol consumption (exceeding 150 g per week), previous symptoms, posterior circulation aneurysms, and larger aneurysms. Focal neurologic signs are usually absent but, when present, may relate either to a focal intracerebral hematoma (from arteriovenous malformations) or to ischemia in the territory of the vessel with a ruptured aneurysm.

**B. Imaging**

A CT scan (preferably with CT angiography) should be performed immediately to confirm that hemorrhage has occurred and to search for clues regarding its source. It is preferable to MRI because it is faster and more sensitive in detecting hemorrhage in the first 24 hours. CT findings sometimes are normal in patients with suspected hemorrhage, and the cerebrospinal fluid must then be examined for the presence of blood or xanthochromia before the possibility of subarachnoid hemorrhage is discounted.

Cerebral arteriography is undertaken to determine the source of bleeding. In general, bilateral carotid and vertebral arteriography are necessary because aneurysms are often multiple, while arteriovenous malformations may be supplied from several sources. The procedure allows an interventional radiologist to treat an underlying aneurysm or arteriovenous malformation by various techniques. If arteriograms show no abnormality, the examination should be repeated after 2 weeks because vasospasm may have prevented detection of an aneurysm or other vascular anomaly during the initial study. CT or MR angiography may also be revealing but is less sensitive than conventional arteriography.

**C. Laboratory and Other Studies**

The cerebrospinal fluid is bloodstained. Electrocardiographic evidence of arrhythmias or myocardial ischemia has been well described and probably relates to excessive sympathetic activity. Peripheral leukocytosis and transient glycosuria are also common findings.

**Treatment**

All patients should be admitted to hospital and seen by a neurologist. The measures outlined below in the section on stupor and coma are applied to comatose patients. Conscious patients are confined to bed, advised against any exertion or straining, treated symptomatically for headache and anxiety, and given laxatives or stool softeners. If there is severe hypertension, the blood pressure can be lowered gradually, but not below a diastolic level of 100 mm Hg. Phenytoin is generally prescribed routinely to prevent seizures. If no cause for the hemorrhage can be identified, medical management is continued for about 6 weeks and is followed by gradual mobilization.

The major aim of treatment is to prevent further hemorrhage. The risk of further hemorrhage from a ruptured aneurysm is greatest within a few days of the first hemorrhage; approximately 20% of patients will have further bleeding within 2 weeks and 40% within 6 months. Definitive treatment, ideally within 2 days of the hemorrhage, requires surgical clipping of the aneurysm base or endovascular treatment by interventional radiologists; the latter is sometimes feasible even for inoperable aneurysms and has a lower morbidity than surgery.

**Complications**

Spontaneous subarachnoid hemorrhage may result in severe complications, so monitoring is necessary, usually in an intensive care unit. Intrathecal thrombolytic therapy, presumably by speeding clearance of extravasated blood, appears to reduce the rate of these complications. Hemiplegia or other focal deficit sometimes may follow aneurysmal bleeding after a delay of 2–14 days due to focal arterial spasm. The etiology of vasospasm is uncertain and likely multifactorial, and it sometimes leads to significant cerebral ischemia or infarction and may further aggravate any existing increase in intracranial pressure. Transcranial Doppler ultrasound may be used to screen noninvasively for vasospasm, but conventional arteriography is required to document and treat vasospasm when the clinical suspicion is high. Calcium channel-blocking agents have helped reduce or reverse vasospasm experimentally, and nimodipine has been shown to reduce, in neurologically normal patients, the incidence of ischemic deficits from arterial spasm without producing any side effects. The dose of nimodipine is 60 mg every 4 hours orally for 21 days. Clazosentan, an endothelin receptor antagonist, has failed to affect vasospasm-related morbidity or mortality; the drug has not yet been approved by the US FDA. After surgical obliteration of all aneurysms, symptomatic vasospasm may also be treated by intravascular volume expansion and induced hypertension; transluminal balloon angioplasty of involved intracranial vessels is also helpful. Aspirin provides no benefit. Results from a randomized trial suggest that the prophylactic administration of intravenous magnesium sulfate, sufficient to achieve serum levels of 4.9–6.1 mg/dL (2–2.5 mmol/L), reduced the risk of transcranial ultrasound-detectable vasospasm and of vasospasm-induced cerebral infarction but did not change overall clinical outcomes.

Acute hydrocephalus, which sometimes occurs due to cerebrospinal fluid outflow disruption by the subarachnoid blood, should be suspected if the patient deteriorates clinically and a repeat CT scan should be done. Acute hydrocephalus frequently causes intracranial hypertension severe enough to require temporary, and less commonly prolonged or permanent, intraventricular cerebrospinal fluid shunting. Renal salt-wasting is another complication of subarachnoid hemorrhage that may develop abruptly during the first several days of hospitalization. The resulting hyponatremia and cerebral edema may exacerbate intracranial hypertension and may require carefully titrated treatment with oral sodium chloride or intravenous hyperosmotic sodium solution. Daily measurement of the serum
sodium level allows for the early detection of this complication. Hypopituitarism may occur as a late complication of subarachnoid hemorrhage.

5. Intracranial Aneurysm

**ESSENTIALS OF DIAGNOSIS**

- Subarachnoid hemorrhage or focal deficit.
- Abnormal imaging studies.

**General Considerations**

Saccular aneurysms ("berry" aneurysms) tend to occur at arterial bifurcations, are frequently multiple (20% of cases), and are usually asymptomatic. They may be associated with polycystic kidney disease and coarctation of the aorta. Risk factors for aneurysm formation include smoking, hypertension, and hypercholesterolemia. Most aneurysms are located on the anterior part of the circle of Willis—particularly on the anterior or posterior communicating arteries, at the bifurcation of the middle cerebral artery, and at the bifurcation of the internal carotid artery. Mycotic aneurysms resulting from septic embolism occur in more distal vessels and often at the cortical surface. The most significant complication of intracranial aneurysms is a subarachnoid hemorrhage, which is discussed in the preceding section. A higher risk of subarachnoid hemorrhage is associated with older age, female sex, "non-white" ethnicity, hypertension, tobacco smoking, high alcohol consumption (exceeding 150 g per week), previous symptoms, posterior circulation aneurysms, and larger aneurysms.

**Clinical Findings**

**A. Symptoms and Signs**

Aneurysms may cause a focal neurologic deficit by compressing adjacent structures. However, most are asymptomatic or produce only nonspecific symptoms until they rupture, at which time subarachnoid hemorrhage results. Its manifestations, complications, and management were outlined in the preceding section.

**B. Imaging**

Definitive evaluation is by angiography (bilateral carotid and vertebral studies), which generally indicates the size and site of the lesion, sometimes reveals multiple aneurysms, and may show arterial spasm if rupture has occurred. Visualization by CT or MR angiography is not usually adequate if operative treatment is under consideration because lesions may be multiple and small lesions are sometimes missed.

**Treatment**

The major aim of treatment is to prevent hemorrhages. Management of ruptured aneurysms was described in the section on subarachnoid hemorrhage. Symptomatic but unruptured aneurysms merit prompt treatment, either surgically or by endovascular techniques, whereas small asymptomatic ones discovered incidentally are often monitored arteriographically and corrected only if they increase in size to over 10 mm.

**When to Refer**

All patients should be referred.

**When to Admit**

- All patients with a subarachnoid hemorrhage.
- All patients for detailed imaging.
- All patients undergoing surgical or endovascular treatment.

6. Arteriovenous Malformations

**ESSENTIALS OF DIAGNOSIS**

- Sudden onset of subarachnoid and intracerebral hemorrhage.
- Distinctive neurologic signs reflect the region of the brain involved.
- Signs of meningeal irritation in patients presenting with subarachnoid hemorrhage.
- Seizures or focal deficits may occur.

**General Considerations**

Arteriovenous malformations are congenital vascular malformations that result from a localized maldevelopment of part of the primitive vascular plexus and consist of abnormal arteriovenous communications without intervening capillaries. They vary in size, ranging from massive lesions that are fed by multiple vessels and involve a large part of the brain to lesions so small that they are hard to identify at arteriography, surgery, or autopsy. In approximately 10% of cases, there is an associated arterial aneurysm, while 1–2% of patients presenting with aneurysms have associated arteriovenous malformations. Clinical presentation may relate to hemorrhage from the malformation or an associated aneurysm or may relate to cerebral ischemia due to diversion of blood by the anomalous arteriovenous shunt or due to venous stagnation. Regional maldevelopment of the brain, compression or distortion of adjacent cerebral tissue by enlarged anomalous vessels, and progressive gliosis due to mechanical and ischemic factors may also be contributory. In addition, communicating or obstructive hydrocephalus may occur and lead to symptoms.

**Clinical Findings**

**A. Symptoms and Signs**

1. **Supratentorial lesions**—Most cerebral arteriovenous malformations are supratentorial, usually lying in the territory of the middle cerebral artery. Initial symptoms consist of hemorrhage in 30–60% of cases, recurrent seizures in 20–40%, headache in 5–25%, and miscellaneous complaints (including focal deficits) in 10–15%. Up to 70% of arteriovenous malformations bleed at some point in their natural history, most commonly before the patient reaches the age of 40 years. This tendency to bleed is unrelated to the lesion site or to the patient’s sex, but small arteriovenous malformations are more likely to bleed than large ones. Arteriovenous malformations that have bled once are more likely to bleed again. Hemorrhage is commonly intracerebral as well as into the subarachnoid space, and it has a fatal outcome in about 10% of cases. Focal or generalized seizures may accompany or follow hemorrhage, or they may be the initial presentation, especially with frontal or parietal arteriovenous malformations. Headaches are especially likely when the external carotid arteries are involved in the malformation. These sometimes simulate migraine but more commonly are nonspecific in character, with nothing about them to suggest an underlying structural lesion.

   In patients presenting with subarachnoid hemorrhage, examination may reveal an abnormal mental status and signs of meningeal irritation. Additional findings may help localize the lesion and sometimes indicate that intracranial pressure is increased. A cranial bruit always suggests the possibility of a cerebral arteriovenous malformation, but bruits may also be found with aneurysms, meningiomas, acquired arteriovenous fistulas, and arteriovenous malformations involving the scalp, calvarium, or orbit. Bruits are best heard over the ipsilateral eye or mastoid region and are of some help in localization but of no help in localization. Absence of a bruit in no way excludes the possibility of arteriovenous malformation.

2. **Infratentorial lesions**—Brainstem arteriovenous malformations are often clinically silent, but they may hemorrhage, cause obstructive hydrocephalus, or lead to progressive or relapsing brainstem deficits. Cerebellar arteriovenous malformations may also be clinically inconspicuous but sometimes lead to cerebellar hemorrhage.

**B. Imaging**

In patients presenting with suspected hemorrhage, CT scanning indicates whether subarachnoid or intracerebral bleeding has recently occurred, helps localize its source, and may reveal the arteriovenous malformation. If the CT scan shows no evidence of bleeding but subarachnoid hemorrhage is diagnosed clinically, the cerebrospinal fluid should be examined.

When intracranial hemorrhage is confirmed but the source of hemorrhage is not evident on the CT scan, arteriography is necessary to exclude aneurysm or arteriovenous malformation. MR and CT angiography are not sensitive enough for this purpose. Even if the findings on CT scan suggest arteriovenous malformation, arteriography is required to establish the nature of the lesion with certainty and to determine its anatomic features so that treatment can be planned. The examination must generally include bilateral opacification of the internal and external carotid arteries and the vertebral arteries. Arteriovenous malformations typically appear as a tangle of vessels with distended tortuous afferent and efferent vessels, a rapid circulation time, and arteriovenous shunting.

   In patients presenting without hemorrhage, CT scan or MRI usually reveals the underlying abnormality, and MRI frequently also shows evidence of old or recent hemorrhage that may have been asymptomatic. The nature and detailed anatomy of any focal lesion identified by these means are delineated by angiography, especially if operative treatment is under consideration.

**C. Laboratory and Other Studies**

Electroencephalography is usually indicated in patients presenting with seizures and may show consistently focal or lateralized abnormalities resulting from the underlying
cerebral arteriovenous malformation. This should be followed by CT scanning.

**Treatment**

Surgical treatment to prevent further hemorrhage is justified in patients with arteriovenous malformations that have bled, provided that the lesion is accessible and the patient has a reasonable life expectancy. Surgical treatment is also appropriate if intracranial pressure is increased and to prevent further progression of a focal neurologic deficit. In patients presenting solely with seizures, anticonvulsant drug treatment is usually sufficient, and operative treatment is unnecessary unless there are further developments.

Definitive operative treatment consists of excision of the arteriovenous malformation if it is surgically accessible. Arteriovenous malformations that are inoperable because of their location are sometimes treated solely by embolization; although the risk of hemorrhage is not reduced, neurologic deficits may be stabilized or even reversed by this procedure. Two other techniques for the treatment of intracerebral arteriovenous malformations are injection of a vascular occlusive polymer through a flow-guided microcatheter and permanent occlusion of feeding vessels by positioning detachable balloon catheters in the desired sites and then inflating them with quickly solidifying contrast material. Stereotactic radiosurgery with the gamma knife or related approaches is also useful in the management of inoperable cerebral arteriovenous malformations.

**When to Refer**

All patients should be referred.

**When to Admit**

- All patients with a subarachnoid or cerebral hemorrhage.
- All patients for detailed imaging.
- All patients undergoing surgical or endovascular treatment.

When to Admit

All patients should be hospitalized.

**8. Spinal Cord Vascular Diseases**

**Infarction of the Spinal Cord**

Infarction of the spinal cord is rare. It typically occurs in the territory of the anterior spinal artery because this vessel, which supplies the anterior two-thirds of the cord, is itself supplied by only a limited number of feeders. Infarction usually results from interrupted flow in one or more of these feeders, eg, with aortic dissection, aortography, polyarteritis, or severe hypotension, or after surgical resection of the thoracic aorta. The paired posterior spinal arteries, by contrast, are supplied by numerous arteries at different levels of the cord. Spinal cord hypoperfusion may lead to a central cord syndrome with distal weakness of lower motor neuron type and loss of pain and temperature appreciation, with preserved posterior column function.

Since the anterior spinal artery receives numerous feeders in the cervical region, infarcts almost always occur caudally. Clinical presentation is characterized by acute onset of flaccid, areflexive paraplegia that evolves after a
few days or weeks into a spastic paraplegia with extensor plantar responses. There is an accompanying dissociated sensory loss, with impairment of appreciation of pain and temperature but preservation of sensations of vibration and position. Treatment is symptomatic.

When to Admit
All patients should be hospitalized.

When to Refer
All patients should be referred.

Epidural or Subdural Hemorrhage
Epidural or subdural hemorrhage may lead to sudden severe back pain followed by an acute compressive myelopathy necessitating urgent spinal MRI or myelography and surgical evacuation. It may occur in patients with bleeding disorders or those who are taking anticoagulant drugs, sometimes following trauma or lumbar puncture. Epidural hemorrhage may also be related to a vascular malformation or tumor deposit.

Spinal Dural Arteriovenous Fistulae
Spinal dural arteriovenous fistulae are congenital lesions that present with spinal subarachnoid hemorrhage or myelodysplasia. Since most of these malformations are located in the thoracolumbar region, they lead to motor and sensory disturbances in the legs and to sphincter disorders. Pain in the legs or back is often severe. Examination reveals an upper, lower, or mixed motor deficit in the legs; sensory deficits are also present and are usually extensive, although occasionally they are confined to radicular distribution. Cervical spinal dural arteriovenous fistulae lead also to symptoms and signs in the arms. Spinal MRI may not detect the spinal dural arteriovenous fistulae, and negative findings do not exclude the diagnosis. Myelography (performed with the patient prone and supine) detects serpiginous filling defects due to enlarged vessels. Selective spinal arteriography confirms the diagnosis. Most lesions are extramedullary, are posterior to the cord (lying either intradurally or extradurally), and can easily be treated by ligation of feeding vessels and excision of the fistulous anomaly or by embolization procedures. Delay in treatment may lead to increased and irreversible disability or to death from recurrent subarachnoid hemorrhage.

When to Refer
All patients should be referred.

When to Admit
All patients should be hospitalized.

General Considerations
Half of all primary intracranial neoplasms (Table 24–5) are gliomas and the remainder are meningoïdomas, pituitary adenomas (see Chapter 26), neurofibromas, and other tumors. Certain tumors, especially neurofibromas, hemangioblastomas, and retinoblastomas, may have a familial basis and occur congenitally. The most familiar syndrome is herniation of the temporal lobe uncus through the tentorial hiatus, which causes compression of the third cranial nerve, midbrain, and posterior cerebral artery. The earliest sign of this is ipsilateral pupillary dilation, followed by stupor, coma, decerebrate posturing, and respiratory arrest. Another important herniation syndrome consists of displacement of the cerebellar tonsils through the foramen magnum, which causes medullary compression leading to apnea, circulatory collapse, and death. Other herniation syndromes are less common and of less clinical importance.

Intracranial tumors also lead to focal deficits depending on their location.

1. Frontal lobe lesions—Tumors of the frontal lobe often lead to progressive intellectual decline, slowing of mental activity, personality changes, and contralateral grasp reflexes. They may lead to expressive aphasia if the posterior part of the left inferior frontal gyrus is involved. Anosmia may also occur as a consequence of pressure on the olfactory nerve. Precentral lesions may cause focal motor seizures or contralateral pyramidal deficits.

2. Temporal lobe lesions—Tumors of the uncinate region may be manifested by seizures with olfactory or
smaller or larger than they are), visual field defects (crossed upper quadrant neuropathy), and auditory illusions or hallucinations. Left-sided lesions may lead to dysnomia and receptive aphasia, while right-sided involvement sometimes disturbs the perception of musical notes and melodies.

Table 24–5. Primary intracranial tumors.

<table>
<thead>
<tr>
<th>Tumor</th>
<th>Clinical Features</th>
<th>Treatment and Prognosis</th>
</tr>
</thead>
<tbody>
<tr>
<td>Glioblastoma multiforme</td>
<td>Presents commonly with nonspecific complaints and increased intracranial pressure. As it grows, focal deficits develop.</td>
<td>Course is rapidly progressive, with poor prognosis. Total surgical removal is usually not possible. Radiation therapy and chemotherapy may prolong survival.</td>
</tr>
<tr>
<td>Astrocytoma</td>
<td>Presentation similar to glioblastoma multiforme but course more protracted, often over several years. Cerebellar astrocytoma may have a more benign course.</td>
<td>Prognosis is variable. By the time of diagnosis, total excision is usually impossible; tumor may be radiosensitive and chemotherapy may also be helpful. In cerebellar astrocytoma, total surgical removal is often possible.</td>
</tr>
<tr>
<td>Medulloblastoma</td>
<td>Seen most frequently in children. Generally arises from roof of fourth ventricle and leads to increased intracranial pressure accompanied by brainstem and cerebellar signs. May seed subarachnoid space.</td>
<td>Treatment consists of surgery combined with radiation therapy and chemotherapy.</td>
</tr>
<tr>
<td>Ependymoma</td>
<td>Glioma arising from the ependyma of a ventricle, especially the fourth ventricle; leads to early signs of increased intracranial pressure. Arises also from central canal of cord.</td>
<td>Tumor is best treated surgically if possible. Radiation therapy may be used for residual tumor.</td>
</tr>
<tr>
<td>Oligodendroglioma</td>
<td>Slow-growing. Usually arises in cerebral hemisphere in adults. Calcification may be visible on skull radiograph.</td>
<td>Treatment is surgical and usually successful. Radiation and chemotherapy may also be helpful if tumor has malignant features.</td>
</tr>
<tr>
<td>Brainstem glioma</td>
<td>Presents during childhood with cranial nerve palsies and then with long tract signs in the limbs. Signs of increased intracranial pressure occur late.</td>
<td>Tumor is inoperable; treatment is by irradiation and shunt for increased intracranial pressure.</td>
</tr>
<tr>
<td>Cerebellar hemangioblastoma</td>
<td>Presents with dysequilibrium, ataxia of trunk or limbs, and signs of increased intracranial pressure. Sometimes familial. May be associated with retinal and spinal vascular lesions, polycythemia, and renal cell carcinoma.</td>
<td>Treatment is surgical. Radiation is used for residual tumor.</td>
</tr>
<tr>
<td>Pineal tumor</td>
<td>Presents with increased intracranial pressure, sometimes associated with impaired upward gaze (Pariapud syndrome) and other deficits indicative of midbrain lesion.</td>
<td>Ventricular decompression by shunting is followed by surgical approach to tumor; irradiation is indicated if tumor is malignant. Prognosis depends on histopathologic findings and extent of tumor.</td>
</tr>
<tr>
<td>Craniopharyngioma</td>
<td>Originates from remnants of Rathke pouch above the sella, depressing the optic chiasm. May present at any age but usually in childhood, with endocrine dysfunction and bitemporal field defects.</td>
<td>Treatment is surgical, but total removal may not be possible. Radiation may be used for residual tumor.</td>
</tr>
<tr>
<td>Acoustic neurinoma</td>
<td>Ipsilateral hearing loss is most common initial symptom. Subsequent symptoms may include tinnitus, headache, vertigo, facial weakness or numbness, and long tract signs. (May be familial and bilateral when related to neurofibromatosis.) Most sensitive screening tests are MRI and brainstem auditory evoked potential.</td>
<td>Treatment is excision by translabyrinthine surgery, cranectomy, or a combined approach. Outcome is usually good.</td>
</tr>
<tr>
<td>Meningioma</td>
<td>Originates from the dura mater or arachnoid; compresses rather than invades adjacent neural structures. Increasingly common with advancing age. Tumor size varies greatly. Symptoms vary with tumor site—eg, unilateral proptosis (sphenoidal ridge); anosmia and optic nerve compression (olfactory groove). Tumor is usually benign and readily detected by CT scanning; may lead to calcification and bone erosion visible on plain radiographs of skull.</td>
<td>Treatment is surgical. Tumor may recur if removal is incomplete.</td>
</tr>
<tr>
<td>Primary cerebral lymphoma</td>
<td>Associated with AIDS and other immunodeficiency states. Presentation may be with focal deficits or with disturbances of cognition and consciousness. May be indistinguishable from cerebral toxoplasmosis.</td>
<td>Treatment is high-dose methotrexate followed by radiation therapy. Prognosis depends on CD4 count at diagnosis.</td>
</tr>
</tbody>
</table>
3. Parietal lobe lesions—Tumors in this location characteristically cause contralateral disturbances of sensation and may cause sensory seizures, sensory loss or inattention, or some combination of these symptoms. The sensory loss is cortical in type and involves postural sensibility and tactile discrimination, so that the appreciation of shape, size, weight, and texture is impaired. Objects placed in the hand may not be recognized (astereognosis). Extensive parietal lobe lesions may produce contralateral hyperpathia and spontaneous pain (thalamic syndrome). Involvement of the optic radiation leads to a contralateral homonymous field defect that sometimes consists solely of lower quadrantanopia. Lesions of the left angular gyrus cause Gerstmann syndrome (a combination of alexia, agraphia, acalculia, right-left confusion, and finger agnosia), whereas involvement of the left submarginal gyrus causes ideational apraxia. Anosognosia (the denial, neglect, or rejection of a paralyzed limb) is seen in patients with lesions of the non-dominant (right) hemisphere. Constructional apraxia and dressing apraxia may also occur with right-sided lesions.

4. Occipital lobe lesions—Tumors of the occipital lobe characteristically produce crossed homonymous hemianopia or a partial field defect. With left-sided or bilateral lesions, there may be visual agnosia both for objects and for colors, while irritative lesions on either side can cause unformed visual hallucinations. Bilateral occipital lobe involvement causes cortical blindness in which there is preservation of pupillary responses to light and lack of awareness of the defect by the patient. There may also be loss of color perception, prosopagnosia (inability to identify a familiar face), simultagnosia (inability to integrate and interpret a composite scene as opposed to its individual elements), and Balint syndrome (failure to turn the eyes to a particular point in space, despite preservation of spontaneous and reflex eye movements). The denial of blindness or a field defect constitutes Anton syndrome.

5. Brainstem and cerebellar lesions—Brainstem lesions lead to cranial nerve palsies, ataxia, incoordination, nystagmus, and pyramidal and sensory deficits in the limbs on one or both sides. Intrinsic brainstem tumors, such as gliomas, tend to produce an increase in intracranial pressure only late in their course. Cerebellar tumors produce marked ataxia of the trunk if the vermis cerebelli is involved and ipsilateral appendicular deficits (ataxia, incoordination and hypotonia of the limbs) if the cerebellar hemispheres are affected.

6. False localizing signs—Tumors may lead to neurologic signs other than by direct compression or infiltration, thereby leading to errors of clinical localization. These false localizing signs include third or sixth nerve palsy and bilateral extensor plantar responses produced by herniation syndromes, and an extensor plantar response occurring ipsilateral to a hemispheric tumor as a result of compression of the opposite cerebral peduncle against the tentorium.

B. Imaging

MRI with gadolinium enhancement is the preferred method to detect the lesion and to define its location, shape, and size; the extent to which normal anatomy is distorted; and the degree of any associated cerebral edema or mass effect. CT scanning with radiocontrast enhancement could be performed; however, it is less helpful than MRI for small lesions or tumors in the posterior fossa. The characteristic appearance of meningiomas on MRI or CT scanning is virtually diagnostic, ie, a lesion in a typical site (parasagittal and sylvian regions, olfactory groove, sphenoidal ridge, tuberculum sellae) that appears as a homogeneous area of increased density in noncontrast scans and enhances uniformly with contrast. Newer neuroimaging techniques may help identify brain tumors by increased blood perfusion (perfusion-weighted MRI, single photon-emission computed tomography, positron-emission tomography) and high metabolism or cell turnover (magnetic resonance spectroscopy, positron-emission tomography), but non-neoplastic diseases, such as stroke and inflammatory or infectious diseases, are sometimes associated with hyperperfusion and hypermetabolism. Diffusion-weighted MRI may also be helpful. Arteriography may show stretching or displacement of normal cerebral vessels by the tumor and the presence of tumor vascularity. The presence of an avascular mass is a nonspecific finding that could be due to tumor, hematoma, abscess, or any space-occupying lesion. In patients with normal hormone levels and an intrasellar mass, angiography is necessary to distinguish with confidence between a pituitary adenoma and an arterial aneurysm.

C. Laboratory and Other Studies

The electroencephalogram provides supporting information concerning cerebral function and may show either a focal disturbance due to the neoplasm or a more diffuse change reflecting altered mental status. Lumbar puncture is rarely necessary; the findings are seldom diagnostic, and the procedure carries the risk of causing a herniation syndrome.

Treatment

Treatment depends on the type and site of the tumor (Table 24–5) and the condition of the patient. Some benign tumors, especially meningiomas discovered incidentally during brain imaging for another purpose, may be monitored with serial annual imaging. For symptomatic tumors, complete surgical removal may be possible if the tumor is extra-axial (eg, meningioma, acoustic neuroma) or is not in a critical or inaccessible region of the brain (eg, cerebellar hemangioblastoma). Surgery also permits the diagnosis to be verified and may be beneficial in reducing intracranial pressure and relieving symptoms even if the neoplasm cannot be completely removed. Clinical deficits are sometimes due in part to obstructive hydrocephalus, in which case simple surgical shunting procedures often produce dramatic benefit. In patients with malignant gliomas, radiation therapy increases median survival rates regardless of any preceding surgery, and its combination with chemotherapy provides additional benefit. Indications for irradiation in the treatment of patients with other primary intracranial neoplasms depend on tumor type...
and accessibility and the feasibility of complete surgical removal. Temozolomide is a commonly used oral and intravenous chemotherapeutic for gliomas, and there is an increasing trend to use monoclonal antibodies as a component of therapy. Corticosteroids help reduce cerebral edema and are usually started before surgery. Herniation is treated with intravenous dexamethasone (10–20 mg as a bolus, followed by 4 mg every 6 hours) and intravenous mannitol (20% solution given in a dose of 1.5 g/kg over about 30 minutes). Anticonvulsants are also commonly administered in standard doses (see Table 24–3) but are not indicated for prophylaxis in patients who have no history of seizures. Long-term neurocognitive deficits may complicate radiation therapy. For those patients whose disease deteriorates despite treatment, palliative care is important (see Chapter 5).

#### When to Refer

All patients should be referred.

#### When to Admit

- All patients with increased intracranial pressure.
- All patients requiring biopsy, surgical treatment, or shunting procedures.

#### 2. Metastatic Intracranial Tumors

##### Cerebral Metastases

Metastatic brain tumors present in the same way as other cerebral neoplasms, ie, with increased intracranial pressure, with focal or diffuse disturbance of cerebral function, or with both of these manifestations. Indeed, in patients with a single cerebral lesion, the metastatic nature of the lesion may only become evident on histopathologic examination. In other patients, there is evidence of widespread metastatic disease, or an isolated cerebral metastasis develops during treatment of the primary neoplasm.

The most common source of intracranial metastasis is carcinoma of the lung; other primary sites are the breast, kidney, skin (melanoma), and gastrointestinal tract. Most cerebral metastases are located supratentorially. Laboratory and radiologic studies used to evaluate patients with metastases are those described for primary neoplasms. They include MRI and CT scanning performed both with and without contrast material. Lumbar puncture is necessary only in patients with suspected carcinomatous meningitis (see below). In patients with verified cerebral metastasis from an unknown primary, investigation is guided by symptoms and signs. In women, mammography is indicated; in men under 50, germ cell origin is sought since both have therapeutic implications.

In patients with only a single, surgically accessible cerebral metastasis who are otherwise well (ie, a high level of functioning and little or no evidence of extracranial disease), it may be possible to remove the lesion and then treat with irradiation; the latter may also be selected as the sole treatment. In patients with multiple metastases or widespread systemic disease, the prognosis is poor; stereotactic radiosurgery, whole-brain radiotherapy, or both, may help in some instances, but in others treatment is palliative only.

---

**Leptomeningeal Metastases (Carcinomatous Meningitis)**

The neoplasms metastasizing most commonly to the leptomeninges are carcinoma of the breast, lymphomas, and leukemia. Leptomeningeal metastases lead to multifocal neurologic deficits, which may be associated with infiltration of cranial and spinal nerve roots, direct invasion of the brain or spinal cord, obstructive hydrocephalus, or some combination of these factors.

The diagnosis is confirmed by examination of the cerebrospinal fluid. Findings may include elevated cerebrospinal fluid pressure, pleocytosis, increased protein concentration, and decreased glucose concentration. Cytologic studies may indicate that malignant cells are present; if not, lumbar puncture should be repeated at least twice to obtain further samples for analysis. CT scans showing contrast enhancement in the basal cisterns or showing hydrocephalus without any evidence of a mass lesion support the diagnosis. Gadolinium-enhanced MRI frequently shows enhancing foci in the leptomeninges. Myelography may show deposits on multiple nerve roots.

Treatment is by irradiation to symptomatic areas, combined with intralesional methotrexate. The long-term prognosis is poor—only about 10% of patients survive for 1 year—and palliative care is therefore important (see Chapter 5).

#### 3. Intracranial Mass Lesions in AIDS Patients

Primary cerebral lymphoma is a common complication in patients with AIDS. This leads to disturbances in
cognition or consciousness, focal motor or sensory deficits, aphasia, seizures, and cranial neuropathies. Similar clinical disturbances may result from cerebral toxoplasmosis, which is also a common complication in patients with AIDS (see Chapters 31 and 35). Neither CT nor MRI findings distinguish these two disorders, and serologic tests for toxoplasmosis are unreliable in AIDS patients. Accordingly, for neurologically stable patients, a trial of treatment for toxoplasmosis with sulfadiazine (100 mg/kg/d up to 8 g/d in four divided doses orally daily) and pyrimethamine (75 mg orally daily for 3 days, then 25 mg orally daily) is recommended for 3 weeks; the imaging studies are then repeated, and if any lesion has improved, the regimen is continued indefinitely. If any lesion does not improve, cerebral biopsy is necessary. Primary cerebral lymphoma is treated with whole-brain irradiation.

Cryptococcal meningitis is a common opportunistic infection in AIDS patients. Clinically, it may resemble cerebral toxoplasmosis or lymphoma, but cranial CT scans are usually normal. The diagnosis is made on the basis of cerebrospinal fluid studies, with positive India ink staining in 75–80% and cryptococcal antigen tests in 95% of cases. Treatment is with amphotericin B plus flucytosine, as set forth in Table 36–1, followed by fluconazole.

## 4. Primary & Metastatic Spinal Tumors

Approximately 10% of spinal tumors are intramedullary. Ependymoma is the most common type of intramedullary tumor; the remainder are other types of glioma. Extramedullary tumors may be extradural or intradural in location. Among the primary extramedullary tumors, neurofibromas and meningiomas are relatively common, are benign, and may be intradural or extradural. Carcinomatous metastases, lymphomatous or leukemic deposits, and myeloma are usually extradural; in the case of metastases, the prostate, breast, lung, and kidney are common primary sites.

Tumors may lead to spinal cord dysfunction by direct compression, by ischemia secondary to arterial or venous obstruction and, in the case of intramedullary lesions, by invasive infiltration.

### Clinical Findings

#### A. Symptoms and Signs

Symptoms usually develop insidiously. Pain is often conspicuous with extradural lesions; is characterized by coughing or straining; may be radicular, localized to the back, or felt diffusely in an extremity; and may be accompanied by motor deficits, paresthesias, or numbness, especially in the legs. Bladder, bowel, and sexual dysfunction may occur. When sphincter disturbances occur, they are usually particularly disabling. Pain, however, often precedes specific neurologic symptoms from epidural metastases.

Examination may reveal localized spinal tenderness. A segmental lower motor neuron deficit or dermatomal sensory changes (or both) are sometimes found at the level of the lesion, while an upper motor neuron deficit and sensory disturbance are found below it.

### B. Imaging

CT myelography or, preferably, MRI with contrast is used to identify and localize the lesion. The combination of known tumor elsewhere in the body, back pain, and either abnormal plain films of the spine or neurologic signs of cord compression is an indication to perform these studies on an urgent basis. Some clinicians proceed to MRI or CT myelography based solely on new back pain in a cancer patient.

### C. Laboratory Findings

The cerebrospinal fluid is often xanthochromic and contains a greatly increased protein concentration with normal cell content and glucose concentration.

#### Treatment

Intramedullary tumors are treated by decompression and surgical excision (when feasible) and by irradiation. The prognosis depends on the cause and severity of cord compression before it is relieved.

Treatment of epidural spinal metastases consists of irradiation, irrespective of cell type. Dexamethasone is also given in a high dosage (eg, 25 mg four times daily for 3 days orally or intravenously, followed by rapid tapering of the dosage, depending on response) to reduce cord swelling and relieve pain. Surgical decompression is reserved for patients with tumors that are unresponsive to irradiation or have previously been irradiated and for cases in which there is some uncertainty about the diagnosis. The long-term outlook is poor, but radiation treatment may at least delay the onset of major disability.

trauma or surgical procedures. The most common infective organisms are streptococci, staphylococci, and anaerobes; mixed infections are not uncommon.

**Clinical Findings**

**A. Symptoms and Signs**

Headache, drowsiness, inattention, confusion, and seizures are early symptoms, followed by signs of increasing intracranial pressure and then a focal neurologic deficit. There may be little or no systemic evidence of infection.

**B. Imaging and Other Investigations**

A CT scan of the head characteristically shows an area of contrast enhancement surrounding a low-density core. Similar abnormalities may be found in patients with metastatic neoplasms. MRI findings often permit earlier recognition of focal cerebritis or an abscess. Arteriography indicates the presence of a space-occupying lesion, which appears as an avascular mass with displacement of normal cerebral vessels. Stereotactic needle aspiration may enable a specific etiologic organism to be identified. Examination of the cerebrospinal fluid does not help in diagnosis and may precipitate a herniation syndrome. Peripheral leukocytosis is sometimes present.

**Treatment**

Treatment consists of intravenous antibiotics, combined with surgical drainage (aspiration or excision) if necessary to reduce the mass effect, or to sometimes to establish the diagnosis. Abscesses smaller than 2 cm can often be cured medically. Broad-spectrum antibiotics, selected based on risk factors and likely organisms, are used if the infecting organism is unknown (see Chapter 33). Initial empiric antibiotic regimens typically include ceftriaxone (2 g intravenously every 12 hours), metronidazole (15 mg/kg intravenously loading dose, followed by 7.5 mg/kg intravenously every 6 hours), and vancomycin (1 g intravenously every 12 hours). The regimen is altered once culture and sensitivity data are available. Antimicrobial treatment is usually continued parenterally for 6–8 weeks, followed by orally for 2–3 months. The patient should be monitored by serial CT scans or MRI every 2 weeks and at deterioration. Dexamethasone (4–25 mg four times daily intravenously or orally, depending on severity, followed by tapering of dose, depending on response) may reduce any associated edema, but intravenous mannitol is sometimes required.

**NONMETASTATIC NEUROLOGIC COMPLICATIONS OF MALIGNANT DISEASE**

A variety of nonmetastatic neurologic complications of malignant disease (see Table 39–2) can be recognized. Metabolic encephalopathy due to electrolyte abnormalities, infections, drug overdose, or the failure of some vital organ may be reflected by drowsiness, lethargy, restlessness, insomnia, agitation, confusion, stupor, or coma. The mental changes are usually associated with tremor, asterixis, and multifocal myoclonus. The electroencephalogram is generally diffusely slowed. Laboratory studies are necessary to detect the cause of the encephalopathy, which must then be treated appropriately.

Immune suppression resulting from either the malignant disease or its treatment (eg, by chemotherapy) predisposes patients to brain abscess, progressive multifocal leukoencephalopathy, meningitis, herpes zoster infection, and other opportunistic infectious diseases. Moreover, an overt or occult cerebrospinal fluid fistula, as occurs with some tumors, may also increase the risk of infection. MRI or CT scanning aids in the early recognition of a brain abscess, but metastatic brain tumors may have a similar appearance. Examination of the cerebrospinal fluid is essential in the evaluation of patients with meningitis but is of no help in the diagnosis of brain abscess.

Cerebrovascular disorders that cause neurologic complications in patients with systemic cancer include nonbacterial thrombotic endocarditis and septic embolization. Cerebral, subarachnoid, or subdural hemorrhages may occur in patients with myelogenous leukemia and may be found in association with metastatic tumors, especially malignant melanoma. Spinal subdural hemorrhage sometimes occurs after lumbar puncture in patients with marked thrombocytopenia.

Disseminated intravascular coagulation occurs most commonly in patients with acute promyelocytic leukemia or with some adenocarcinomas and is characterized by a fluctuating encephalopathy, often with associated seizures, that frequently progresses to coma or death. There may be few accompanying neurologic signs. Venous sinus thrombosis, which usually presents with convulsions and headaches, may also occur in patients with leukemia or lymphoma. Examination commonly reveals papilledema and focal or diffuse neurologic signs. Anticonvulsants, anticoagulants, and drugs to lower the intracranial pressure may be of value.

Autoimmune paraneoplastic disorders occur when the immune system reacts against neuronal antigens expressed by tumor cells. The clinical manifestations depend on the autoantibody. Symptoms may precede those due to the neoplasm itself. Several distinct syndromes are common, including paraneoplastic cerebellar degeneration, limbic encephalitis, encephalomyelitis, anti-NMDA receptor-associated encephalitis, opsoclonus/myoclonus, sensory neuronopathy, and dermatomyositis.

**Paraneoplastic cerebellar degeneration** occurs most commonly in association with carcinoma of the lung, but also in breast and gynecologic cancers and Hodgkin lymphoma. Typically, there is a pancerbellar syndrome causing dysarthria, nystagmus, and ataxia of the trunk and limbs. The disorder is associated with anti-Yo, -Tr, -voltage-gated calcium channel (VGCC), and -Zic antibodies. Treatment is of the underlying malignant disease. **Limbic encephalitis** is characterized by impaired recent memory, disturbed affect, hallucinations, and seizures, occurs in some patients with tumors of the lungs, breast, thymus, and germ cells.
Associated antibodies include anti-Hu, -Ma2, -CV2/CRMP5, -voltage-gated potassium channel (VGKC), -AMPA receptor, and -GABA<sub>a</sub> receptor. A more generalized encephalomyelitis occurs with anti-Hu, -CV2/CRMP5, -Ma2, and -ampiphysin antibodies in the context of a similar spectrum of tumors. Anti-NMDA receptor-associated encephalitis causes a characteristic syndrome of severe psychiatric symptoms, dyskinesias, dysautonomia, and hyperventilation, and is frequently associated with ovarian teratoma. Opsoclonus/myoclonus, a syndrome of involuntary, erratic, and conjugate saccadic eye movements and myoclonic movements of the limbs, occurs in patients with lung, breast, and gynecologic tumors, often without an identifiable antibody. Sensory neuronopathy, typically caused by anti-Hu antibodies in small cell lung cancer or other carcinomas, manifests itself with asymmetric, multifocal sensory nerve root deficits leading to pain, numbness, sensory ataxia, and sometimes hearing loss. Dermatomyositis (see Chapter 20) or the Lambert-Eaton myasthenic syndrome (discussed below) may be seen in patients with underlying carcinoma. Identification of an antibody is not always possible in a suspected autoimmune paraneoplastic condition, and a search for an underlying neoplasm should not be deterred. Treatment of the neoplasm takes priority and offers the best hope for stabilization or improvement of the neurologic symptoms, which often are not completely reversible. Specific treatment of the antibody-mediated symptoms by intravenous immunoglobulin (IVIG) administration, plasmapheresis, corticosteroids, or other immunosuppressive regimens, is frequently attempted despite limited efficacy. Encephalitides involving antibodies directed against neuronal cell surface antigens, such as VGKC or AMPA, NMDA, or GABA<sub>a</sub> receptors, can occur either as paraneoplastic phenomena or in isolation, and typically respond well to immunotherapy.

**PSEUDOTUMOR CEREBRI**
(Benign Intracranial Hypertension)

**ESSENTIALS OF DIAGNOSIS**

- Headache, worse on straining.
- Visual obscurations or diplopia may occur.
- Examination reveals papilledema.
- Abducens palsy is commonly present.

**General Considerations**

There are many causes of pseudotumor cerebri. Thrombosis of the transverse venous sinus as a noninfectious complication of otitis media or chronic mastoiditis is one cause, and sagittal sinus thrombosis may lead to a clinically similar picture. Other causes include chronic pulmonary disease, systemic lupus erythematosus, uremia, endocrine disturbances such as hypoparathyroidism, hypothyroidism, or Addison disease, vitamin A toxicity, and the use of tetracycline or oral contraceptives. Cases have also followed withdrawal of corticosteroids after long-term use. In most instances, however, no specific cause can be found, and the disorder remits spontaneously after several months. This idiopathic variety—known as idiopathic intracranial hypertension—occurs most commonly among overweight women aged 20–44. In all cases, screening for a space-occupying lesion of the brain is important.

**Clinical Findings**

**A. Symptoms and Signs**

Symptoms consist of headache, diplopia, and other visual disturbances due to papilledema and abducens nerve dysfunction. Pulse-synchronous tinnitus may also occur. Examination reveals the papilledema and some enlargement of the blind spots, but patients otherwise look well.

**B. Imaging**

Investigations reveal no evidence of a space-occupying lesion. CT scan shows small or normal ventricles. MR venography is helpful in screening for thrombosis of the intracranial venous sinuses.

**C. Laboratory Findings**

Lumbar puncture confirms the presence of intracranial hypertension, but the cerebrospinal fluid is normal. Laboratory studies help exclude some of the other causes mentioned earlier.

**Treatment**

Untreated intracranial hypertension sometimes leads to secondary optic atrophy and permanent visual loss. Acetazolamide (250–500 mg orally three times daily, increasing slowly to a maintenance dose of 1000–2000 mg daily, divided two to four times daily) reduces formation of cerebrospinal fluid and can be used to start treatment. Like acetazolamide, the antiepileptic drug topiramate (Table 24–3) is a carbonic anhydrase inhibitor and was shown to be similarly effective in an open label study; topiramate has the added benefit of causing weight loss. Corticosteroids (eg, prednisone, 60–80 mg daily) may also be necessary. Obese patients should be advised to lose weight. Repeated lumbar puncture to lower the intracranial pressure by removal of cerebrospinal fluid is effective as a temporizing measure, but pharmacologic approaches to treatment provide better long-term relief. Treatment is monitored by checking visual acuity and visual fields, funduscopic appearance, and pressure of the cerebrospinal fluid. The disorder may worsen after a period of stability, indicating the need for long-term follow-up.

If medical treatment fails to control the intracranial pressure, surgical placement of a lumboperitoneal or
ventriculoperitoneal shunt or optic nerve sheath fenestration should be undertaken to preserve vision.

In addition to the above measures, any specific cause of intracranial hypertension requires appropriate treatment. Thus, hormone therapy should be initiated if there is an underlying endocrine disturbance. Discontinuing the use of tetracycline, oral contraceptives, or vitamin A will allow for resolution of intracranial hypertension due to these agents. If corticosteroid withdrawal is responsible, the medication should be reintroduced and then tapered more gradually.

**When to Refer**

All patients should be referred.

**When to Admit**

All patients requiring shunt placement or optic nerve sheath fenestration should be hospitalized.

**SELECTED NEUROCUTANEOUS DISEASES**

Because the nervous system develops from the epithelial layer of the embryo, a number of congenital diseases include both neurologic and cutaneous manifestations. Among these disorders, three are discussed below, and von Hippel–Lindau disease is discussed in Chapter 26.

1. **Tuberous Sclerosis**

Tuberous sclerosis may occur sporadically or on a familial basis with autosomal dominant inheritance. The disease is caused by mutations that inactivate either the TSC1 (hamartin) gene on chromosome 9 or the TSC2 (tuberin) gene on chromosome 16, resulting in constitutive expression of mTOR (mammalian target of rapamycin) and impaired tumor suppression in multiple tissues. Neurologic presentation is with seizures and progressive psychomotor retardation beginning in early childhood. The cutaneous abnormality, adenoma sebaceum, becomes manifest usually between 5 and 10 years of age and typically consists of reddened nodules on the face (cheeks, nasolabial folds, sides of the nose, and chin) and sometimes on the forehead and neck. Other typical cutaneous lesions include subungual fibromas, shagreen patches (leathery plaques of subepidermal fibrosis, situated usually on the trunk), and leaf-shaped hypopigmented spots. Associated abnormalities include retinal lesions and tumors, benign rhabdomyomas of the heart, lung cysts, benign tumors in the viscera, and bone cysts. The disease is slowly progressive and leads to increasing mental deterioration. There is no specific treatment, but anticonvulsant drugs may help in controlling seizures.

2. **Neurofibromatosis**

Neurofibromatosis may occur either sporadically or on a familial basis with autosomal dominant inheritance. Two distinct forms are recognized: Type 1 (Recklinghausen disease) is characterized by multiple hyperpigmented macules and neurofibromas, and results from mutations in the NF1 gene on chromosome 17. Type 2 is characterized by eighth nerve tumors, often accompanied by other intracranial or intraspinal tumors, and is associated with mutations in the NF2 (merlin) gene on chromosome 22.

Neurologic presentation is usually with symptoms and signs of tumor. Multiple neurofibromas characteristically are present and may involve spinal or cranial nerves, especially the eighth nerve (Figure 24–1). Examination of the superficial cutaneous nerves usually reveals palpable mobile nodules. In some cases, there is an associated marked overgrowth of subcutaneous tissues (plexiform neuromas), sometimes with an underlying bony abnormality. Associated cutaneous lesions include axillary freckling and patches of cutaneous pigmentation (café au lait spots). Malignant degeneration of neurofibromas occasionally occurs and may lead to peripheral sarcomas. Meningiomas, gliomas (especially optic nerve gliomas), bone cysts, pheochromocytomas, scoliosis, and obstructive hydrocephalus may also occur.

**Figure 24–1. Neurofibromatosis.** (Courtesy of Jack Resnick, Sr, MD, used, with permission, from Usatine RP, Smith MA, Mayeaux EJ, Jr, Chumley H, Tysinger J. The Color Atlas of Family Medicine. McGraw-Hill, 2009.)
3. Sturge-Weber Syndrome

Sturge-Weber syndrome consists of a congenital, usually unilateral, cutaneous capillary angioma involving the upper face, leptomeningeal angiomatosis and, in many patients, choroidal angioma. It has no sex predilection and usually occurs sporadically. The cutaneous angioma sometimes has a more extensive distribution over the head and neck and is often quite disfiguring, especially if there is associated overgrowth of connective tissue. Focal or generalized seizures are the usual neurologic presentation and may commence at any age. There may be contralateral homonymous hemianopia, hemiparesis and hemisensory disturbance, ipsilateral glaucoma, and mental subnormality. Skull radiographs taken after the first 2 years of life usually reveal gyriform (“tramline”) intracranial calcification, especially in the parieto-occipital region, due to mineral deposition in the cortex beneath the intracranial angioma.

Treatment is aimed at controlling seizures pharmacologically, but surgical treatment may be necessary. Ophthalmologic advice should be sought concerning the management of choroidal angioma and of increased intraocular pressure.

MOVEMENT DISORDERS

1. Benign Essential (Familial) Tremor

ESSENTIALS OF DIAGNOSIS

- Postural tremor of hands, head, or voice.
- Family history common.
- May improve temporarily with alcohol.
- No abnormal findings other than tremor.

General Considerations

The cause of benign essential tremor is uncertain, but it is sometimes inherited in an autosomal dominant manner. Responsible genes have been identified at 3q13, 2p22-p25, and 6p23.

Clinical Findings

Tremor may begin at any age and is enhanced by emotional stress. The tremor usually involves one or both hands, the head, or the hands and head, while the legs tend to be spared. Examination reveals no other abnormalities. Ingestion of a small quantity of alcohol commonly provides remarkable but short-lived relief by an unknown mechanism.

Although the tremor may become more conspicuous with time, it generally leads to little disability. Occasionally, it interferes with manual skills and leads to impairment of handwriting. Speech may also be affected if the laryngeal muscles are involved.

Treatment

Treatment is often unnecessary. When it is required because of disability, propranolol may be helpful but will need to be continued indefinitely in doses of 60–240 mg daily orally. However, intermittent therapy is sometimes useful in patients whose tremor becomes exacerbated in specific predictable situations.Primidone may be helpful when propranolol is ineffective, but patients with essential tremor are often very sensitive to it. Therefore, the starting dose is 50 mg daily orally, and the daily dose is increased by 50 mg every 2 weeks depending on the patient’s response; a maintenance dose of 125 mg three times daily orally is commonly effective. Occasional patients do not respond to these measures but are helped by alprazolam (up to 3 mg daily in divided doses), topiramate (titrated up to a dose of 400 mg daily orally in divided doses over about 8 weeks). gabapentin (1800 mg daily orally in divided doses), mirtazapine (15 or 30 mg at night orally), or clozapine (30–50 mg twice daily orally). Other antiepileptic agents including levetiracetam and zonisamide are reportedly sometimes effective. Botulinum toxin A may reduce tremor, but adverse effects include dose-dependent weakness of the injected muscles. Pregabalin was recently shown to be ineffective.

Disabling tremor unresponsive to medical treatment may be helped by high-frequency thalamic stimulation to one or both hemispheres, according to the laterality of symptoms. Subdural motor cortex stimulation has also been effective in a small trial.

When to Refer

All patients should be referred.

When to Admit

Patients requiring surgical treatment (deep brain stimulator placement) should be hospitalized.

2. Parkinsonism

ESSENTIALS OF DIAGNOSIS

- Any combination of tremor, rigidity, bradykinesia, and progressive postural instability.
- Cognitive impairment is sometimes prominent.
General Considerations

Parkinsonism is a relatively common disorder that occurs in all ethnic groups, with an approximately equal sex distribution. The most common variety, idiopathic Parkinson disease, begins most often between 45 and 65 years of age and is a progressive disease.

Etiology

Parkinsonism may rarely occur on a familial basis, and the parkinsonian phenotype may result from mutations of several different genes (alpha-synuclein, parkin, LRRK2, DJ1, and PINK1). Mutations in LRRK2 also account for some cases of apparently sporadic Parkinson disease. Postencephalitic parkinsonism is becoming increasingly rare. Exposure to certain toxins (eg, manganese dust, carbon disulfide) and severe carbon monoxide poisoning may lead to parkinsonism. Typical parkinsonism has occurred in individuals who have taken 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) for recreational purposes. This compound is converted in the body to a neurotoxin that selectively destroys dopaminergic neurons in the substantia nigra. Reversible parkinsonism may develop in patients receiving neuroleptic drugs (see Chapter 25), reserpine, or metoclopramide. Only rarely is hemiparkinsonism the presenting feature of a progressive space-occupying lesion.

In idiopathic Parkinson disease, dopamine depletion due to degeneration of the dopaminergic nigrostriatal system leads to an imbalance of dopamine and acetylcholine, which are neurotransmitters normally present in the corpus striatum. Treatment is directed at redressing this imbalance by blocking the effect of acetylcholine with anticholinergic drugs or by the administration of levodopa, the precursor of dopamine. The serum urate level may be a prognostic indicator—the rate of progression declines as the urate level increases. Prior use of ibuprofen is associated with a decreased risk of developing Parkinson disease.

Clinical Findings

Tremor, rigidity, bradykinesia, and postural instability are the cardinal features of parkinsonism and may be present in any combination. There may also be a mild decline in intellectual function. The tremor of about four to six cycles per second is most conspicuous at rest, is enhanced by emotional stress, and is often less severe during voluntary activity. Although it may ultimately be present in all limbs, the tremor is commonly confined to one limb or to the limbs on one side for months or years before it becomes more generalized. In some patients, tremor is absent.

Rigidity (an increase in resistance to passive movement) is responsible for the characteristically flexed posture seen in many patients, but the most disabling symptoms of parkinsonism are due to bradykinesia, manifested as a slowness of voluntary movement and a reduction in automatic movements such as swinging of the arms while walking. Curiously, however, effective voluntary activity may briefly be regained during an emergency (eg, the patient is able to leap aside to avoid an oncoming motor vehicle).

Clinical diagnosis of the well-developed syndrome is usually simple. The patient has a relatively immobile face with widened palpebral fissures, infrequent blinking, and a certain fixity of facial expression. Seborrhea of the scalp and face is common. There is often mild blepharoclonus, and a tremor may be present about the mouth and lips. Repetitive tapping (about twice per second) over the bridge of the nose produces a sustained blink response (Myerson sign). Other findings may include saliva drooling from the mouth, perhaps due to impairment of swallowing; soft and poorly modulated voice; a variable rest tremor and rigidity in some or all of the limbs; slowness of voluntary movements; impairment of fine or rapidly alternating movements; and micrographia. There is typically no muscle weakness (provided that sufficient time is allowed for power to be developed) and no alteration in the tendon reflexes or plantar responses. It is difficult for the patient to arise from a sitting position and begin walking. The gait itself is characterized by small shuffling steps and a loss of the normal automatic arm swing; there may be unsteadiness on turning, difficulty in stopping, and a tendency to fall.

Differential Diagnosis

Diagnostic problems may occur in mild cases, especially if tremor is minimal or absent. For example, mild hypokinesia or slight tremor is commonly attributed to old age. Depression, with its associated expressionless face, poorly modulated voice, and reduction in voluntary activity, can be difficult to distinguish from mild parkinsonism, especially since the two disorders may coexist; in some cases, a trial of antidepressant drug therapy is necessary. The family history, the character of the tremor, and lack of other neurolologic signs should distinguish essential tremor from parkinsonism. Wilson disease can be distinguished by its early age at onset, the presence of other abnormal movements, Kayser-Fleischer rings, and chronic hepatitis, and by increased concentrations of copper in the tissues. Huntington disease presenting with rigidity and bradykinesia may be mistaken for parkinsonism unless the family history and accompanying dementia are recognized. In multisystem atrophy (previously called the Shy-Drager syndrome), autonomic insufficiency (leading to postural hypotension, anhidrosis, disturbances of sphincter control, erectile dysfunction, etc) may be accompanied by parkinsonism, pyramidal deficits, lower motor neuron signs, or cerebellar dysfunction. In progressive supranuclear palsy, bradykinesia and rigidity are accompanied by a supranuclear disorder of eye movements, pseudobulbar palsy, pseudo-emotional lability (pseudobulbar affect), and axial dystonia. Jakob-Creutzfeldt disease may be accompanied by features of parkinsonism, but dementia is usual, myoclonic jerking is common, ataxia and pyramidal signs may be conspicuous, and the electroencephalographic findings are usually characteristic. In corticobasal degeneration, asymmetric parkinsonism is accompanied by conspicuous signs of cortical dysfunction (eg, apraxia, sensory inattention, dementia, aphasia).

Treatment

Treatment is symptomatic. There is great interest in developing disease-modifying therapies, and trials of several
putative neuroprotective agents are in progress, as are various trials of gene therapy.

**A. Medical Measures**

Drug treatment is not required early in the course of Parkinson disease, but the nature of the disorder and the availability of medical treatment for use when necessary should be discussed with the patient.

1. **Amantadine**—Patients with mild symptoms but no disability may be helped by amantadine. This drug improves all of the clinical features of parkinsonism, but its mode of action is unclear. Side effects include restlessness, confusion, depression, skin rashes, edema, nausea, constipation, anorexia, postural hypotension, and disturbances of cardiac rhythm. However, these are relatively uncommon with the usual dose (100 mg twice daily orally). It also ameliorates dyskinesias resulting from chronic levodopa therapy.

2. **Anticholinergic drugs**—Anticholinergics are more helpful in alleviating tremor and rigidity than bradykinesia. Treatment is started with a small dose (Table 24–6) and gradually increased until benefit occurs or side effects limit further increments. If treatment is ineffective, the drug is gradually withdrawn and another preparation then tried.

Common side effects include dryness of the mouth, nausea, constipation, palpitations, cardiac arrhythmias, urinary retention, confusion, agitation, restlessness, drowsiness, mydriasis, increased intraocular pressure, and defective accommodation.

Anticholinergic drugs are contraindicated in patients with prostatic hyperplasia, narrow-angle glaucoma, or obstructive gastrointestinal disease and are often tolerated poorly by the elderly. They are best avoided whenever cognitive impairment or a predisposition to delirium exists.

3. **Levodopa**—Levodopa, which is converted in the body to dopamine, improves all of the major features of parkinsonism, including bradykinesia, but does not stop progression of the disorder. The most common early side effects of levodopa are nausea, vomiting, and hypotension, but cardiac arrhythmias may also occur. Dyskinesias, restlessness, confusion, and other behavioral changes tend to occur somewhat later and become more common with time. Levodopa-induced dyskinesias may take any conceivable form, including chorea, athetosis, dystonia, tremor, tics, and myoclonus. An even later complication is the “on-off phenomenon,” in which abrupt but transient fluctuations in the severity of parkinsonism occur unpredictably but frequently during the day. The “off” period of marked dyskinesia has been shown to relate in some instances to falling plasma levels of levodopa. During the “on” phase, dyskinesias are often conspicuous but mobility is increased.

Carbidopa, which inhibits the enzyme responsible for the breakdown of levodopa to dopamine, does not cross the blood-brain barrier. When levodopa is given in combination with carbidopa, the extracerebral breakdown of levodopa is diminished. This reduces the amount of levodopa required daily for beneficial effects, and it lowers the incidence of nausea, vomiting, hypotension, and cardiac irregularities. Such a combination does not prevent the development of the “on-off phenomenon,” and the incidence of other side effects (dyskinesias or psychiatric complications) may actually be increased.

Sinemet, a commercially available preparation that contains carbidopa and levodopa in a fixed ratio (1:10 or 1:4), is generally used. Treatment is started with a small dose—eg, one tablet of Sinemet 25/100 (containing 25 mg of carbidopa and 100 mg of levodopa) three times daily—and gradually increased depending on the response. Sinemet CR is a controlled-release formulation (containing 25 or 50 mg of carbidopa and 100 or 200 mg of levodopa). It is sometimes helpful in reducing fluctuations in clinical response to treatment and in reducing the frequency with which medication must be taken. The commercially available combination of levodopa with both carbidopa and entacapone (Stalevo) may also be helpful in this context and is discussed in the following section on COMT inhibitors. Response fluctuations are also reduced by keeping the daily intake of protein at the recommended minimum and taking the main protein meal as the last meal of the day.

The dyskinesias and behavioral side effects of levodopa are dose-related, but reduction in dose may eliminate any therapeutic benefit. Levodopa-induced dyskinesias may also respond to amantadine or possibly levetiracetam.

Levodopa therapy is contraindicated in patients with psychotic illness or narrow-angle glaucoma. It should not be given to patients taking monoamine oxidase A inhibitors or within 2 weeks of their withdrawal, because hypertensive crises may result. Levodopa should be used with care in patients with suspected malignant melanomas or with active peptic ulcers because of concerns that it may exacerbate these disorders.

4. **Dopamine agonists**—Dopamine agonists act directly on dopamine receptors, and their use in parkinsonism is associated with a lower incidence of the response fluctuations and dyskinesias that occur with long-term levodopa therapy. They were previously reserved for patients who had either become refractory to levodopa or developed the “on-off phenomenon.” However, they are now best given either before the introduction of levodopa or with a low dose of Sinemet 25/100 (carbidopa 25 mg and levodopa

100 mg), one tablet three times daily when dopaminergic therapy is first introduced; the dose of Sinemet is kept constant, while the dose of the agonist is gradually increased. Bromocriptine, an ergot derivative is not widely used in the United States because of side effects, including anorexia; nausea; vomiting; constipation; postural hypotension; digital vasospasm; cardiac arrhythmias; various dyskinesias and mental disturbances; headache; nasal congestion; erythromelalgia; pulmonary infiltrates; and pericardial, pleural, or pulmonary fibrosis. In 2007, the manufacturer of pergolide, another ergot derivative and dopamine agonist, withdrew the drug from the US market after two studies showed that serious cardiac valvular abnormalities developed in some patients while taking the drug.

Pramipexole and ropinirole are two newer dopamine agonists that are not ergot derivatives. They are effective in early Parkinson disease as well as in advanced stages of the disease. In each case, the daily dose is built up gradually. Pramipexole is started at a dosage of 0.125 mg three times daily orally, and the dose is doubled after 1 week and again after another week; the daily dose is then increased by 0.75 mg at weekly intervals depending on response and tolerance. Most patients require between 0.5 and 1.5 mg three times daily orally. Ropinirole is begun in a dosage of 0.25 mg three times daily orally, and the total daily dose is increased at weekly intervals by 0.75 mg until the fourth week and by 1.5 mg thereafter. Most patients require between 2 and 8 mg three times daily for benefit. Adverse effects include fatigue, somnolence, nausea, peripheral edema, dyskinesias, confusion, and postural hypotension. Less commonly, an irresistible urge to sleep may occur, sometimes in inappropriate and hazardous circumstances. Impulse control disorders involving gambling, shopping, or sexual activity have also been related to use of dopamine agonists. Extended-release, once-daily formulations of pramipexole and ropinirole are now available with similar efficacy and tolerability as the immediate release versions.

5. Selective monoamine oxidase inhibitors—Rasagiline, a selective monoamine oxidase B inhibitor, has a clear symptomatic benefit in a daily oral dose of 1 mg, taken in the morning; it may also be used for adjunctive therapy in patients with response fluctuations to levodopa. Selegiline (5 mg orally with breakfast and lunch) is another monoamine oxidase B inhibitor that is sometimes used as adjunctive treatment for parkinsonism. By inhibiting the metabolic breakdown of dopamine, these drugs may improve fluctuations or declining response to levodopa. Although it is sometimes advised that tyramine-rich foods be avoided when either rasagiline or selegiline is taken because of the theoretical possibility of a hypertensive (“cheese”) effect, there is no clinical evidence to support the need for such dietary precautions when they are taken at the recommended dosage.

Studies have suggested (but failed to show conclusively) that rasagiline may slow the progression of Parkinson disease, and it appears to delay the need for other symptomatic therapies. For these reasons, rasagiline is often started early, particularly for patients who are young or have mild disease. However, the FDA has rejected an expansion of rasagiline’s indication to include disease modification.

6. COMT inhibitors—Catecholamine-β-methyltransferase (β-MT) inhibitors reduce the metabolism of levodopa to 3-β-methyldopa and thereby alter the plasma pharmacokinetics of levodopa, leading to more sustained plasma levels and more constant dopaminergic stimulation of the brain. Two such agents, tolcapone and entacapone, are currently available and may be used as an adjunct to levodopa-carbidopa in patients with response fluctuations or an otherwise inadequate response. Treatment results in reduced response fluctuations, with a greater period of responsiveness to administered levodopa; however, the use of these agents does not delay the eventual development of levodopa-induced dyskinesias. Tolcapone is given in a dosage of 100 mg or 200 mg three times daily orally, and entacapone is given as 200 mg with each dose of Sinemet (levodopa-carbidopa).

With either preparation, the dose of Sinemet taken concurrently may have to be reduced by up to one-third to avoid side effects such as dyskinesias, confusion, hypotension, and syncope. Diarrhea is sometimes troublesome. Because rare cases of fulminant hepatic failure have followed its use, tolcapone should be avoided in patients with preexisting liver disease. Serial liver function tests should be performed at 2-week intervals for the first year and at longer intervals thereafter in patients receiving the drug—as recommended by the manufacturer. Hepatotoxicity has not been reported with entacapone, which is therefore the preferred agent, and serial liver function tests are not required.

Stalevo is the commercial preparation of levodopa combined with both carbidopa and entacapone. It is best used in patients already stabilized on equivalent doses of carbidopa/levodopa and entacapone. It is priced at or below the price of the individual ingredients (ie, carbidopa/levodopa and entacapone) and has the added convenience of requiring fewer tablets to be taken daily. It is available in three strengths: Stalevo 50 (12.5 mg of carbidopa, 50 mg of levodopa, and 200 mg of entacapone), Stalevo 100 (25 mg of carbidopa, 100 mg of levodopa, and 200 mg of entacapone), and Stalevo 150 (37.5 mg of carbidopa, 150 mg of levodopa, and 200 mg of entacapone).

7. Atypical antipsychotics—Confusion and psychotic symptoms may occur as a side effect of dopaminergic therapy or as a part of the underlying illness. They often respond to atypical antipsychotic agents, which have few extrapyramidal side effects and do not block the effects of dopaminergic medication. Olanzapine, quetiapine, and risperidone may be tried, but the most effective of these agents is clozapine, a dibenzodiazepine derivative. Clozapine may rarely cause marrow suppression, and weekly blood counts are therefore necessary for patients taking it. The patient is started on 6.25 mg at bedtime and the dosage increased to 25–100 mg/d as needed. In low doses, it may also improve iatrogenic dyskinesias.

B. General Measures

Physical therapy or speech therapy helps many patients. Cognitive impairment and psychiatric symptoms may be helped by a cholinesterase inhibitor, such as rivastigmine (3–12 mg orally daily or 4.6 or 9.5 mg/24 hours transdermally daily). The quality of life can often be improved by
the provision of simple aids to daily living, eg, rails or banisters placed strategically about the home, special table cutlery with large handles, nonslip rubber table mats, and devices to amplify the voice.

C. Surgical Measures

Thalamotomy or pallidotomy may help patients who become unresponsive to medical treatment or have intolerable side effects from antiparkinsonian agents, especially if they have no evidence of diffuse vascular disease or significant cognitive decline. Ablative surgery should generally be confined to one side because the morbidity is considerably greater after bilateral procedures. Because of their morbidity, ablative procedures have generally been supplanted by deep brain stimulation.

D. Brain Stimulation

High-frequency stimulation of the subthalamic nuclei or globus pallidus internus may benefit all the major features of the disease. Electrical stimulation of the brain has the advantage over ablative procedures of being reversible and of causing minimal or no damage to the brain, and is therefore the preferred surgical approach to treatment. There is no evidence that the natural history of Parkinson disease is affected. Deep brain stimulation is reserved for patients without cognitive impairment or psychiatric disorder who have a good response to levodopa but in whom dyskinesias or response fluctuations are problematic. It frequently takes 3–6 months after surgery to adjust stimulator programming and to achieve optimal results. Side effects include depression, apathy, impulsivity, executive dysfunction, and decreased verbal fluency in a subset of patients.

E. Gene Therapy

Injections of adeno-associated viruses encoding various human genes have been made into the subthalamic nucleus or putamen in various phase I and phase II trials. These trials are currently ongoing, but the procedure appears to be safe. Early evidence suggests that transfer of the gene for glutamic acid decarboxylase (the enzyme that produces the inhibitory neurotransmitter GABA) into the subthalamic nucleus improves motor function in patients with Parkinson disease, but it is unclear whether there is any greater benefit than subthalamic deep-brain stimulation.

When to Refer
All patients should be referred.

When to Admit
Patients requiring surgical treatment should be admitted.

3. Huntington Disease

General Considerations
Huntington disease is characterized by chorea and dementia. It is inherited in an autosomal dominant manner and occurs throughout the world, in all ethnic groups, with a prevalence rate of about 5 per 100,000. There is an expanded and unstable CAG trinucleotide repeat in the huntingtin gene at 4p16.3; longer repeat lengths correspond to an earlier age of onset and faster disease progression.

Clinical Findings
A. Symptoms and Signs
Clinical onset is usually between 30 and 50 years of age. The disease is progressive and usually leads to a fatal outcome within 15–20 years. The initial symptoms may consist of either abnormal movements or intellectual changes, but ultimately both occur. The earliest mental changes are often behavioral, with irritability, moodiness, antisocial behavior, or a psychiatric disturbance, but a more obvious dementia subsequently develops. The dyskinesia may initially be no more than an apparent fidgetiness or restlessness, but eventually choreiform movements and some dystonic posturing occur. Progressive rigidity and akinesia (rather than chorea) sometimes occur in association with dementia, especially in cases with childhood onset.

B. Imaging
CT scanning or MRI usually demonstrates cerebral atrophy and atrophy of the caudate nucleus in established cases.
Positron emission tomography (PET) has shown reduced striatal metabolic rate.

**Differential Diagnosis**

The diagnosis is established with a widely available genetic test, although such testing should be pursued under the guidance of a licensed genetic counselor. Chorea developing with no family history of choreoathetosis should not be attributed to Huntington disease, at least not until other causes of chorea have been excluded clinically and by appropriate laboratory studies. Nongenetic causes of chorea include stroke, systemic lupus erythematosus and related disorders, paraneoplastic syndromes, infection with HIV, and various medications. In younger patients, self-limiting Sydenham chorea develops after group A streptococcal infections on rare occasions. If a patient presents solely with progressive intellectual failure, it may not be possible to distinguish Huntington disease from other causes of dementia unless there is a characteristic family history or a dyskinesia develops.

**Huntington disease–like (HDL) disorders** resemble Huntington disease but the CAG trinucleotide repeat number of the huntingtin gene is normal. There are autosomal dominant (HDL1, a familial prion disease involving a mutation in the PRNP gene on chromosome 20; and HDL2, a triplet repeat disease involving the gene for junc-trophilin-3 on chromosome 16) and recessive forms (HDL3, 4p15.3).

A clinically similar autosomal dominant disorder (dentatorubral-pallidoluysian atrophy), manifested by chorea, dementia, ataxia, and myoclonic epilepsy, is uncommon except in persons of Japanese ancestry. It is due to a mutation in the ATN1 gene mapping to 12p13.31. Treatment is as for Huntington disease.

**Treatment**

There is no cure for Huntington disease; progression cannot be halted; and treatment is purely symptomatic. The reported biochemical changes suggest a relative underactivity of neurons containing gamma-aminobutyric acid (GABA) and acetylcholine or a relative overactivity of dopaminergic neurons. Tetrabenazine, a drug that interferes with the vesicular storage of biogenic amines, is widely used to treat the dyskinesia. The starting dose is 12.5 mg twice or three times daily orally, increasing by 12.5 mg every 5 days depending on response and tolerance; the usual maintenance dose is 25 mg three times daily. Side effects include depression, postural hypotension, drowsiness, and parkinsonian features; tetrabenazine should not be given within 14 days of taking monoamine oxidase inhibitors and is not indicated for the treatment of levodopa-induced dyskiniesias. Reserpine is similar in depleting central monoamines but has more peripheral effects and a worse side-effect profile, making its use problematic in Huntington disease; if utilized, the dose is built up gradually to between 2 mg and 5 mg orally daily, depending on the response. Treatment with drugs blocking dopamine receptors, such as phenothiazines or haloperidol, may control the dyskinesia and any behavioral disturbances.

Haloperidol treatment is usually begun with a dose of 1 mg once or twice daily orally, which is then increased every 3 or 4 days depending on the response; alternatively, atypical antipsychotic agents such as quetiapine (increasing from 25 mg daily orally up to 100 mg twice daily orally as tolerated) may be tried. Amantadine in a dose of 200 mg to 400 mg daily orally is sometimes helpful for chorea. Behavioral disturbances may respond to clozapine. Attempts to compensate for the relative GABA deficiency by enhancing central GABA activity or to compensate for the relative cholinergic underactivity by giving choline chloride have not been therapeutically helpful. Neuroprotective strategies are being explored.

Offspring should be offered genetic counseling. Genetic testing permits presymptomatic detection and definitive diagnosis of the disease.

**When to Refer**

All patients should be referred.

---

**4. Idiopathic Torsion Dystonia**

**ESSENTIALS OF DIAGNOSIS**

- Dystonic movements and postures.
- Normal birth and developmental history. No other neurologic signs.
- Investigations (including CT scan or MRI) reveal no cause of dystonia.

**General Considerations**

Idiopathic torsion dystonia may occur sporadically or on a hereditary basis, with autosomal dominant, autosomal recessive, and X-linked recessive modes of transmission. One responsible gene is located at 9q34 (and has been named DYT1) and involves a unique mutation consisting of a GAG deletion in the major dominantly inherited disorder, and maps to the long arm of the X chromosome in the X-linked recessive form; the responsible gene in the autosomal recessive disorder is unknown. Symptoms may begin in childhood or later and persist throughout life.
Clinical Findings

The disorder is characterized by the onset of abnormal movements and postures in a patient with a normal birth and developmental history, no relevant past medical illness, and no other neurologic signs. Investigations (including CT scan) reveal no cause for the abnormal movements. Dystonic movements of the head and neck may take the form of torticollis, blepharospasm, facial grimacing, or forced opening or closing of the mouth. The limbs may also adopt abnormal but characteristic postures. The age at onset influences both the clinical findings and the prognosis. With onset in childhood, there is usually a family history of the disorder, symptoms commonly commence in the legs, and progression is likely until there is severe disability from generalized dystonia. In contrast, when onset is later, a positive family history is unlikely, initial symptoms are often in the arms or axial structures, and severe disability does not usually occur, although generalized dystonia may ultimately develop in some patients. If all cases are considered together, about one-third of patients eventually become so severely disabled that they are confined to chair or bed, while another one-third are affected only mildly.

Differential Diagnosis

Before a diagnosis of idiopathic torsion dystonia is made, it is imperative to exclude other causes of dystonia. Perinatal anoxia, birth trauma, and kernicterus are common causes of dystonia, but abnormal movements usually then develop before the age of 5, the early development of the patient is usually abnormal, and a history of seizures is not unusual. Moreover, examination may reveal signs of mental retardation or pyramidal deficit in addition to the movement disorder. Dystonic posturing may also occur in Wilson disease, Huntington disease, or parkinsonism; as a sequela of encephalitis lethargica or previous neuroleptic drug therapy; and in certain other disorders. In these cases, diagnosis is based on the history and accompanying clinical manifestations.

Treatment

Idiopathic torsion dystonia usually responds poorly to drugs. Levodopa, diazepam, baclofen, carbamazepine, amantadine, or anticholinergic medication (in high dosage) is occasionally helpful; if not, a trial of treatment with tetrabenazine, phenothiazines, or haloperidol may be worthwhile. In each case, the dose has to be individualized, depending on response and tolerance. However, the doses of these latter drugs that are required for benefit lead usually to mild parkinsonism. Pallidal deep brain stimulation is helpful for medically refractory dystonia and has a lower morbidity than stereotactic thalamotomy, which is sometimes helpful in patients with predominantly unilateral limb dystonia. Potential adverse events of deep brain stimulation include cerebral infection or hemorrhage, broken leads, affective changes, and dysarthria.

A distinct variety of dominantly inherited dystonia, caused by a mutation in the gene for GTP cyclohydrolase I on chromosome 14q, is remarkably responsive to levodopa.

When to Refer

All patients should be referred.

When to Admit

Patients requiring surgical treatment should be admitted.

5. Focal Torsion Dystonia

A number of the dystonic manifestations that occur in idiopathic torsion dystonia may also occur as isolated phenomena. They are best regarded as focal dystonias that either occur as formes frustes of idiopathic torsion dystonia in patients with a positive family history or represent a focal manifestation of the adult-onset form of that disorder when there is no family history. Mapping of responsible genes to chromosome 8 (DYT6) and chromosome 18 (DYT7) has been reported in some instances of cervical or cranial dystonia. Medical treatment is generally unsatisfactory. A trial of the drugs used in idiopathic torsion dystonia is worthwhile, however, since a few patients do show some response. In addition, with restricted dystonias such as blepharospasm or torticollis, local injection of botulinum A toxin into the overactive muscles may produce worthwhile benefit for several weeks or months and can be repeated as needed.

Both blepharospasm and oromandibular dystonia may occur as an isolated focal dystonia. The former is characterized by spontaneous involuntary forced closure of the eyelids for a variable interval. Oromandibular dystonia is manifested by involuntary contraction of the muscles about the mouth causing, for example, involuntary opening or closing of the mouth, roving or protruding tongue movements, and retraction of the platysma.

Spasmodic torticollis, usually with onset between 25 and 50 years of age, is characterized by a tendency for the neck to twist to one side. This initially occurs episodically, but eventually the neck is held to the side. Spontaneous resolution may occur in the first year or so. The disorder is otherwise usually lifelong. Selective section of the spinal accessory nerve and the upper cervical nerve roots is sometimes helpful if medical treatment is unsuccessful. Local injection of botulinum A toxin provides benefit in most cases.

Writer’s cramp is characterized by dystonic posturing of the hand and forearm when the hand is used for writing and sometimes when it is used for other tasks, eg, playing the piano or using a screwdriver or eating utensils. Drug treatment is usually unrewarding, and patients are often best advised to learn to use the other hand for activities requiring manual dexterity. Injections of botulinum A toxin are helpful in some instances.

6. Myoclonus

Occasional myoclonic jerks may occur in anyone, especially when drifting into sleep. General or multifocal myoclonus
is common in patients with idiopathic epilepsy and is especially prominent in certain hereditary disorders characterized by seizures and progressive intellectual decline, such as the lipid storage diseases. It is also a feature of various rare degenerative disorders, notably Ramsay Hunt syndrome, and is common in subacute sclerosing panencephalitis and Jakob-Creutzfeldt disease. Generalized myoclonic jerking may accompany uremic and other metabolic encephalopathies, result from therapy with levodopa or cyclic antidepressants, occur in alcohol or drug withdrawal states, or follow anoxic brain damage. It also occurs on a hereditary or sporadic basis as an isolated phenomenon in otherwise healthy subjects.

Segmental myoclonus is a rare manifestation of a focal spinal cord lesion. It may also be the clinical expression of *epilepsia partialis continua*, a disorder in which a repetitive foci epileptic discharge arises in the contralateral sensorimotor cortex, sometimes from an underlying structural lesion. An electroencephalogram is often helpful in clarifying the epileptic nature of the disorder, and CT or MRI scan may reveal the causal lesion.

Myoclonus may respond to certain anticonvulsant drugs, especially valproic acid, or to one of the benzodiazepines, particularly clonazepam (see Table 24–3). It may also respond to piracetam (up to 16.8 g daily). Myoclonus following anoxic brain damage is often responsive to oxitriptan (5-hydroxytryptophan), an investigational agent that is the precursor of serotonin, and sometimes to clonazepam (0.125–0.5 mg once daily or ropinirole 0.25–4 mg once daily) 2 to 3 hours before bedtime, or with benzodiazepines, such as clonazepam. Gabapentin (starting with 300 mg daily, increasing to approximately 1800 mg daily depending on response and tolerance), pregabalin (150–300 mg divided twice to three times daily), or gabapentin enacarbil (600 mg extended release daily) are related drugs that improve symptoms. Levodopa is helpful but may lead to an augmentation of symptoms, so that its use is generally reserved for those who do not respond to other measures. In some instances, opioids are required to control symptoms.

**7. Wilson Disease**

In this metabolic disorder, abnormal movement and posture may occur with or without coexisting signs of liver involvement. Psychiatric and neuropsychological manifestations are common. Wilson disease is discussed in Chapter 16.

**8. Drug-Induced Abnormal Movements**

Phenothiazines, butyrophenones, and metoclopramide may produce a wide variety of abnormal movements, including parkinsonism, akathisia (ie, motor restlessness), acute dystonia, chorea, and tardive dyskinesias or dystonia; several of these are also produced by aripiprazole. These complications are discussed in Chapter 25. Chorea may also develop in patients receiving levodopa, bromocriptine, anticholinergic drugs, phenytoin, carbamazepine, lithium, amphetamines, or oral contraceptives, and it resolves with withdrawal of the offending substance. Similarly, dystonia may be produced by levodopa, bromocriptine, lithium, or carbamazepine; and parkinsonism by reserpine and tetrabenazine. Postural tremor may occur with a variety of drugs, including epinephrine, isoproterenol, theophylline, caffeine, lithium, thyroid hormone, tricyclic antidepressants, and valproic acid.

**9. Restless Legs Syndrome**

This disorder may occur as a primary (idiopathic) disorder or in relation to Parkinson disease, pregnancy, iron deficiency anemia, peripheral neuropathy (especially uremic or diabetic), or periodic leg movements of sleep. It may have a hereditary basis, and several genetic loci have been associated with the disorder (12q12–q21, 14q13–q21, 9p24–p22, 2q33, 20p13, 6p21, and 2p14–p13). Restlessness and curious sensory disturbances lead to an irresistible urge to move the limbs, especially during periods of relaxation. Disturbed nocturnal sleep and excessive daytime somnolence may result. Therapy is with nonergot dopamine agonists, such as pramipexole (0.125–0.5 mg once daily or ropinirole 0.25–4 mg once daily) 2 to 3 hours before bedtime, or with benzodiazepines, such as clonazepam. Gabapentin (starting with 300 mg daily, increasing to approximately 1800 mg daily depending on response and tolerance), pregabalin (150–300 mg divided twice to three times daily), or gabapentin enacarbil (600 mg extended release daily) are related drugs that improve symptoms. Levodopa is helpful but may lead to an augmentation of symptoms, so that its use is generally reserved for those who do not respond to other measures. In some instances, opioids are required to control symptoms.

**10. Gilles de la Tourette Syndrome**

*Multiple motor and phonic tics.*

*Symptoms begin before age 21 years.*

*Tics occur frequently for at least 1 year.*

*Tics vary in number, frequency, and nature over time.*

**Clinical Findings**

Motor tics are the initial manifestation in 80% of cases and most commonly involve the face, whereas in the remaining
20%, the initial symptoms are phonic tics; ultimately a combination of different motor and phonic tics develop in all patients. These are noted first in childhood, generally between the ages of 2 and 15. Motor tics occur especially about the face, head, and shoulders (e.g., sniffing, blinking, frowning, shoulder shrugging, head thrusting, etc.). Phonic tics commonly consist of grunts, barks, hisses, throat-clearing, coughs, etc., but sometimes also of verbal utterances including coprolalia (obscene speech). There may also be echolalia (repetition of the speech of others), echopraxia (imitation of others’ movements), and palilalia (repetition of words or phrases). Some tics may be self-mutilating in nature, such as nail-biting, hair-pulling, or biting of the lips or tongue. The disorder is chronic, but the course may be punctuated by relapses and remissions. Obsessive-compulsive behaviors are commonly associated and may be more disabling than the tics themselves. A family history is sometimes obtained, and a mutation in the histidine decarboxylase gene on chromosome 15 was recently reported in one family with an autosomal dominant form of the disease. Prior reports of a linkage to chromosome 13q have been called into question.

Examination usually reveals no abnormalities other than the tics. In addition to obsessive-compulsive behavior disorders, psychiatric disturbances may occur because of the associated cosmetic and social embarrassment. The diagnosis of the disorder is often delayed for years, the tics being interpreted as psychiatric illness or some other form of abnormal movement. Patients are thus often subjected to unnecessary treatment before the disorder is recognized. The tic-like character of the abnormal movements and the absence of other neurologic signs should differentiate this disorder from other movement disorders presenting in childhood. Wilson disease, however, can simulate the condition and should be excluded.

**Treatment**

Treatment is symptomatic and may need to be continued indefinitely. Cognitive behavioral therapy or other forms of behavioral intervention can be effective alone or in combination with pharmacotherapy. 
α-Adrenergic agonists, such as clonidine (start 0.05 mg orally at bedtime, titrating to 0.3–0.4 mg orally daily, divided three to four times per day) or guanfacine (start 0.5 mg orally at bedtime, titrating to a maximum of 3–4 mg orally daily, divided twice daily) are first-line therapies because of a favorable side-effect profile compared with typical antipsychotics, which are the only FDA-approved therapies for the disorder. Topiramate has shown promise in a double-blind, placebo-controlled study, and the use of tetrabenazine has been described but not rigorously tested. Atypical antipsychotics, including risperidone and aripiprazole, have shown possible efficacy and may be tried before the typical antipsychotic agents. When a typical antipsychotic is required in cases of severe tics, haloperidol is generally regarded as the drug of choice. It is started in a low dose (0.25 mg daily orally) that is gradually increased (by 0.25 mg every 4 or 5 days) until there is maximum benefit with a minimum of side effects or until side effects limit further increments. A total daily oral dose of between 2 mg and 8 mg is usually optimal, but higher doses are sometimes necessary. Fluphenazine (2–15 mg orally daily) or pimozide (1–10 mg orally daily) are alternatives. Typical antipsychotics can cause significant weight gain and carry a risk of tardive dyskinesias and other long-term, potentially irreversible motor side effects.

Injection of botulinum toxin type A at the site of the most distressing tics is sometimes worthwhile. Bilateral high-frequency deep brain stimulation at various sites has been helpful in some, otherwise intractable, cases.

**When to Refer**

All patients with Gilles de la Tourette syndrome should be referred.

**When to Admit**

Patients undergoing surgical (deep brain stimulation) treatment should be admitted.

**Dementia**

**ESSENTIALS OF DIAGNOSIS**

- Progressive intellectual decline.
- Not due to delirium or psychiatric disease.
- Age is the main risk factor, followed by family history and vascular disease risk factors.

**General Considerations**

Dementia is a progressive decline in intellectual function that is severe enough to compromise social or occupational functioning. “Mild cognitive impairment” describes a decline that has not resulted in a change in the level of function. Although a few patients identify a precipitating event, most experience an insidious onset and gradual progression of symptoms.

Dementia typically begins after age 60, and the prevalence doubles approximately every 5 years thereafter; in persons aged 85 and older, around half have dementia. In most, the cause of dementia is acquired, either as a sporadic primary neurodegenerative disease or as the result of another disorder, such as stroke. Other risk factors for dementia include family history, diabetes mellitus and other vascular disease risk factors, and a history of significant head injury. Dementia is more prevalent among women, but this is accounted for by their longer life expectancy. Education and ongoing intellectual stimulation may
be protective, perhaps by promoting a "cognitive reserve," an improved capacity to compensate for insidious neurodegeneration.

Dementia is distinct from delirium and psychiatric disease. Delirium is an acute confusional state that often occurs in response to an identifiable trigger, such as drug or alcohol intoxication or withdrawal (eg, Wernicke encephalopathy, described below); medication side effects (especially drugs with anticholinergic properties, antihistamines, benzodiazepines, sleeping aids, opioids, neuroleptics, corticosteroids, and other sedative or psychotropic agents), infection (consider occult urinary tract infection or pneumonia in elderly patients), metabolic disturbance (including an electrolyte abnormality; hypoglycemia or hyperglycemia; or a nutritional, endocrine, renal, or hepatic disorder), sleep deprivation, or other neurologic disease (seizure, including a postictal state, or stroke). A delirium typically involves fluctuating level of arousal, including drowsiness or agitation, and it improves after removal or treatment of the precipitating factor. Patients with dementia are especially susceptible to episodes of delirium, but recognition of the dementia is not possible until the delirium lifts. For this reason, dementia is typically diagnosed in outpatients who are otherwise medically stable, rather than in acutely ill patients in the hospital.

Psychiatric disease sometimes leads to complaints of impaired cognition. Impaired attention is usually to blame, and in some patients with depression or anxiety, poor focus and concentration may even be a primary complaint. The symptoms should improve with appropriate psychiatric treatment. Mood disorders are commonly seen in patients with neurodegenerative disease and in some cases are an early symptom. There is some evidence that a persistent, untreated mood disorder may predispose to the development of an age-related dementia, and psychiatric symptoms can clearly exacerbate cognitive impairment in patients who already have dementia; therefore, suspicion of dementia should not distract from appropriate screening for and treatment of depression or anxiety.

Clinical Findings
A. Symptoms and Signs

Physicians should be aware that a patient's insight into a cognitive change may be vague or absent, and collateral history is essential to a proper evaluation. As patients age, primary care clinicians should inquire periodically about the presence of any cognitive symptoms.

Symptoms depend on the area of the brain affected. Short-term memory loss, involving the repeating of questions or stories and a diminished ability to recall the details of recent conversations or events, frequently results from pathologic changes in the hippocampus. Word-finding difficulty often involves difficulty recalling the names of people, places, or objects, with low-frequency words affected first, eventually resulting in speech laden with pronouns and circumlocutions. This problem is thought to arise from pathology at the temporoparietal junction of the left hemisphere. Problems with articulation, fluency, comprehension, or word meaning are anatomically distinct and less common. Visuospatial dysfunction may result in poor navigation and getting lost in familiar places, impaired recognition of previously familiar faces and buildings, or trouble discerning an object against a background. The right parietal lobe is one of the brain areas implicated in such symptoms. Executive dysfunction may manifest by easy distractibility, impulsivity, mental inflexibility, concrete thought, slowed processing speed, poor planning and organization, or impaired judgment. Localization may vary and could include the frontal lobes or subcortical areas like the basal ganglia or cerebral white matter. Apathy or indifference, separate from depression, is common and may have a similar anatomy as executive dysfunction. Apraxia, or the loss of learned motor behaviors, may result from dysfunction of the frontal or parietal lobes, especially the left parietal lobe.

The time of symptom onset must be established, but subtle, early symptoms are often apparent only in retrospect. Another event, such as an illness or hospitalization, may lead to a new recognition of existing symptoms. Symptoms often accumulate over time, and the nature of the earliest symptom is most helpful in forming the differential diagnosis. The history should establish risk factors for dementia, including family history, other chronic illnesses, and vascular disease risk factors. Finally, it is important to document the patient's current capacity to perform basic and instrumental activities of daily living (see Chapter 4) and to note the extent of decline from the premorbid level of function. Indeed, it is this functional assessment that defines the presence and severity of a dementia.

The physical examination is important to identify any occult medical illness. In addition, eye movement abnormalities, parkinsonism (see above), or other motor abnormalities may help identify an underlying neurologic condition. The workup should prioritize the exclusion of conditions that are reversible or require separate therapy. Screening for depression is necessary, along with imaging and laboratory workup, as indicated below.

B. Neuropsychological Assessment

Brief quantification of cognitive impairment is indicated in a patient complaining of cognitive symptoms. The Folstein Mini Mental State Exam (MMSE) is commonly used, and can be administered in approximately 5 minutes. The Montreal Cognitive Assessment takes slightly longer and may be slightly more sensitive. These tests are useful because they are objective and widely used, but both have important limitations: they are insensitive to mild cognitive impairment, they may be biased negatively by the presence of language or attention problems, and they do not correlate with functional capacity.

An evaluation by a trained neuropsychologist or psychometrist may be appropriate. The goal of such testing is to enhance localization by defining the cognitive domains that are impaired as well as to quantify the degree of impairment. There is no standard battery of tests, but a variety of metrics are commonly used to assess all of the symptom types highlighted above. Assessments are most accurate when a patient is well-rested, comfortable, and otherwise medically stable.
In an asymptomatic patient, there is no screening guideline. Because occult cognitive impairment can lead to morbidity through isolation and poor attentiveness to basic needs (for instance, in an elderly individual living alone), periodic screening is prudent for patients in their 70s and older: Ask the patient to repeat three simple nouns (not referring to objects in the room), then to draw a clock face with numbers in the correct place and the hands indicating a time of 11:10, and finally to recall the three nouns; recall of fewer than three words or any abnormality in the clock drawing may signify the need to continue with the full MMSE and to pursue further questioning and workup.

**C. Imaging**

Brain imaging is indicated in any patient with a new, progressive cognitive complaint. The goal is to exclude occult cerebrovascular disease, tumor, or other identifiable structural abnormality, rather than to provide positive evidence of a neurodegenerative disease. Global or local brain atrophy may be worse than expected for age and could suggest a particular neurodegenerative process, but such findings are rarely specific. MRI is preferred, but CT scan will suffice; no contrast is necessary. If MRI is obtained, then diffusion-weighted sequences may be helpful if acute stroke or prion disease is a consideration.

Positron-emission tomography (PET) with fluorodeoxyglucose (FDG) may identify particular brain structures that are hypometabolic and thus likely to harbor pathology. PET imaging does not confirm or exclude any specific cause of dementia but may be useful as an element of the workup in specific clinical circumstances, such as discriminating between Alzheimer disease and frontotemporal dementia in a patient with some symptoms of each. PET imaging with a radiolabeled ligand for β-amyloid, one of the pathologic proteins in Alzheimer disease, is nearing FDA approval and may soon be available. This technique may be quite helpful in diagnosing Alzheimer disease in younger patients. However, after age 60 or 70, amyloid plaques can accumulate in the absence of cognitive impairment; thus, the specificity of a positive amyloid scan diminishes with age. Single photon-emission computed tomography offers similar information as FDG-PET but is less sensitive.

**D. Laboratory Findings**

Serum levels of vitamin B₁₂, free T₄, and thyroid-stimulating hormone should be measured for any patient with cognitive symptoms. A serum rapid plasma regain (RPR) used to be obtained routinely, but now is done only if there is a risk factor or suspicion for a remote, untreated syphilis infection. Other testing should be driven by clinical suspicion, and often includes a complete blood count, serum electrolytes, glucose, and lipid profile. Also prudent is age-appropriate cancer screening.

Other tests are available if Alzheimer disease is a consideration: ApoE genotyping is clinically available, and the presence of one or two ApoE ε4 alleles indicates an increased risk of Alzheimer disease. Importantly, the gene does not cause Alzheimer disease; familial Alzheimer disease is rare and is caused by mutations in the amyloid precursor protein or presenilin genes. Finding an ApoE ε4 allele in a young patient with dementia might raise the index of suspicion for Alzheimer disease. Obtaining a genotype in an elderly patient is unlikely to be helpful, and doing so in an asymptomatic patient as a marker of risk for Alzheimer disease is inappropriate until a preventive therapy becomes available. Spinal fluid protein measurements are also now clinically available. Levels of β-amyloid decrease and tau protein increase in Alzheimer disease, but the sensitivity and specificity at discriminating from other causes of dementia is uncertain.

**Differential Diagnosis**

In elderly patients with gradually progressive cognitive symptoms and no other complaint or sign, a neurodegenerative disease is likely (Table 24–7). Decline beginning before age 60, rapid progression, fluctuating course, unintended weight loss, systemic complaints, or other unexplained symptoms or signs raise suspicion for another process. In this case, the differential is broad and includes infection or inflammatory disease (consider a lumbar puncture to screen for cells or antibodies in the spinal fluid), neoplasm or a paraneoplastic condition, endocrine or metabolic disease, drugs or toxins, or other conditions.

**Normal pressure hydrocephalus** is a difficult diagnosis to establish. Symptoms include gait apraxia (sometimes described as a “magnetic” gait, as if the feet are stuck to the floor), urinary incontinence, and dementia. CT scanning or MRI of the brain reveals ventricles that are enlarged in obvious disproportion to sulcal widening and overall brain atrophy. When drainage of a large volume (30–50 mL) of cerebrospinal fluid by lumbar puncture results in objective improvement of gait (such as in the time to walk 20 feet), then consideration is often given to the placement of a lumbo-peritoneal shunt. Unfortunately, gait disorders, incontinence, and cognitive dysfunction often occur together nonspecifically in elderly patients, and distinguishing normal pressure hydrocephalus from cerebral atrophy is not straightforward. Because of the surgical risks associated with shunt placement, as well as a strong risk for future shunt malfunction requiring further surgical intervention, the procedure should be avoided except in clear-cut cases. In general, it is the gait apraxia that is most likely to improve after surgery; the cognitive impairment is least likely to respond.

**Treatment**

**A. Nonpharmacologic Approaches**

Aerobic exercise (45 minutes most days of the week) and frequent mental stimulation may reduce the rate of functional decline and decrease the demented patient’s caregiving needs, and these interventions may reduce the risk of dementia in normal individuals. The most efficacious manner of mental stimulation is a matter of debate: maintaining as active a role in the family and community as practically possible is most likely to be of benefit, emphasizing activities at which the patient feels confident. Patients with neurodegenerative diseases have a limited capacity to regain lost skills; for instance, memory drills in a patient

• Short-term memory impairment is early and prominent in most cases  
• Variable deficits of executive function, visuospatial function, and language |
| Vascular dementia                | Multifocal ischemic change                                                 | • Stepwise or progressive accumulation of cognitive deficits in association with repeated strokes  
• Symptoms depend on localization of strokes |
| Dementia with Lewy bodies        | Histologically indistinguishable from Parkinson disease: α-synuclein-containing Lewy bodies occur in the brainstem, midbrain, olfactory bulb, and neocortex. Alzheimer pathology may coexist. | • Cognitive dysfunction, with prominent visuospatial and executive deficits  
• Psychiatric disturbance, with anxiety, visual hallucinations, and fluctuating delirium  
• Parkinsonian motor deficits with or after other features  
• Cholinesterase inhibitors lessen delirium; poor tolerance of many psychoactive medications, including neuroleptics and dopaminergics |
| Frontotemporal dementia (FTD)    | Neuropathology is variable and defined by the protein found in intraneuronal aggregates. Tau protein, TAR DNA-binding protein 43 (TDP-43), or fused-in-sarcoma (FUS) protein account for most cases. | • Peak incidence in the sixth decade; approximately equal to Alzheimer disease as a cause of dementia in patients under 60 years old.  
• Familial cases result from mutations in genes for tau, progranulin, or others  
**Behavioral variant FTD**  
• Deficits in empathy, social comportment, insight, abstract thought, and executive function  
• Behavior is disinhibited, impulsive, and ritualistic, with prominent apathy and increased interest in sex or sweet/fatty foods  
• Relative preservation of memory  
• Focal right frontal atrophy  
• Association with amyotrophic lateral sclerosis  

**Semantic dementia**  
• Deficits in word-finding, single word comprehension, object and category knowledge, and face recognition  
• Behaviors may be rigid, ritualistic, or similar to behavioral variant FTD  
• Focal, asymmetric temporal pole atrophy  

**Progressive nonfluent aphasia**  
• Speech is effortful with dysarthria, phonemic errors, sound distortions, and poor grammar  
• Focal extrapyramidal signs and apraxia of the right arm and leg are common  
• On a diagnostic and pathological continuum with corticobasal degeneration  
• Focal left frontal atrophy |

with Alzheimer disease are more likely to lead to frustration than benefit and studies show that computerized cognitive training does not improve cognition or function in demented patients.

**B. Cognitive Symptoms**

Cholinesterase inhibitors are first-line therapy for Alzheimer disease and dementia with Lewy bodies. They provide mild, symptomatic treatment for cognitive dysfunction and may prolong the capacity for independence. However, they do not prevent disease progression. Commonly used medications include donepezil (start at 5 mg orally daily for 4 weeks, then increase to 10 mg daily; a 23 mg daily dose is newly approved for moderate to severe Alzheimer disease, although its additional efficacy over the 10-mg dose is modest); rivastigmine (start at 1.5 mg orally twice daily, then increasing every 2 weeks by 1.5 mg twice daily to a goal of 3–6 mg twice daily); and galantamine (start at 4 mg orally twice daily, then increasing every 4 weeks by 4 mg twice daily to a goal of 8–12 mg twice daily). Cholinesterase inhibitors are not given for frontotemporal dementia because they may
worsen behavioral symptoms. Nausea and diarrhea are common side effects; syncope and cardiac dysrhythmia are uncommon but more serious. An ECG is often obtained before and after starting therapy, particularly in a patient with cardiac disease or a history of syncope.

Memantine (start at 5 mg orally daily, then increase by 5 mg per week up to a target of 10 mg twice daily) is approved for the treatment of moderate to severe Alzheimer disease. In frontotemporal dementia, some open-label studies support its use, and blinded, placebo-controlled trials are underway. There is some evidence that memantine may improve cognition and behavior among patients with dementia with Lewy bodies.

Disease-modifying drugs are not yet available for Alzheimer disease. Active and passive immunotherapy directed against β-amyloid is currently being explored. Such treatment appears to increase the risk for meningeval inflammation or brain edema, especially in patients with an ApoE ε4 allele, and it remains to be seen whether a counterbalancing benefit exists; phase III trials are ongoing.

C. Mood and Behavioral Disturbances

Selective serotonin reuptake inhibitors are generally safe and well-tolerated in elderly, cognitively impaired patients, and they may be efficacious for the treatment of depression, anxiety, or agitation. However, paroxetine should be avoided because it has anticholinergic effects. Other antidepressant agents, such as bupropion or venlafaxine, may also be tried. Studies on the efficacy of antidepressant therapy in this population are conflicting, but these medications are better tolerated than some alternatives (discussed here).

Insomnia is common, and trazodone (25–50 mg orally at bedtime as needed) can be safe and effective. Over-the-counter antihistamine hypnotics must be avoided, along with benzodiazepines, because of their tendency to worsen cognition and precipitate delirium. Other prescription hypnotics such as zolpidem may result in similar adverse reactions.

For agitation, impulsivity, and other behaviors that interfere with safe caregiving, causes of delirium (detailed above) should first be considered. When no reversible trigger is identified, treatment should be approached in a staged manner. Behavioral interventions, such as reorientation and distraction from anxiety-provoking stimuli, are first-line. Ensure that the patient is kept active during the day with both physical exercise and mentally stimulating activities, and that there is adequate sleep at night. Reassess the level of caregiving, and consider increasing the time spent directly with an attendant. Next, ensure that appropriate pharmacologic treatment of cognition and mood is maximized. Finally, as a last resort, when other measures prove insufficient and the patient’s behaviors raise safety concerns, consider low doses of an atypical antipsychotic medication, such as quetiapine (start 25 mg orally daily as needed, increasing to two to three times daily as needed); even though atypical agents cause extrapyramidal side effects less frequently than typical antipsychotics, they should be used with particular caution in a patient at risk for falls, especially if parkinsonian signs are already present. Regularly scheduled dosing is not recommended, and if implemented should be reassessed on a frequent basis (eg, weekly), with attempts to taper off as tolerated. There is an FDA black box warning against the use of all antipsychotic medications in demented patients because of an association with death from cardiovascular and infectious diseases, and other causes. Benzodiazepines, such as lorazepam (0.5 mg as needed, up to one to two times daily) may be used as an alternative, but they may sometimes worsen rather than ameliorate agitation.

Finally, psychostimulants like methylphenidate have been studied as a means to treat apathy in dementia. While such treatment may be of benefit to selected patients, the possibility of causing agitation or cardiovascular strain limits routine use.

Special Circumstances

A. Rapidly Progressive Dementia

When dementia develops quickly, with obvious decline over a few weeks to a few months, the syndrome may be classified as a rapidly progressive dementia. The differential diagnosis for typical dementias is still relevant, but additional etiologies must be considered, including prion disease; infections; toxins; neoplasms; and autoimmune and inflammatory diseases, including corticosteroid-responsive (Hashimoto) encephalopathy and antibody-mediated paraneoplastic syndromes. Workup should begin with brain MRI with contrast and diffusion-weighted imaging, routine laboratory studies (serum vitamin B12, free T4, and thyroid-stimulating hormone levels), serum RPR, HIV antibody, Lyme serology, rheumatologic tests (erythrocyte sedimentation rate, C-reactive protein, and antinuclear antibody), anti-thyroglobulin and anti-thyroperoxidase antibody levels, paraneoplastic autoimmune antibodies, and cerebrospinal fluid studies (cell count and differential; protein and glucose levels; protein electrophoresis for oligoclonal bands; IgG index [spinal-fluid-to-serum gamma-globulin level] ratio; and VDRL). Depending on the clinical context, it may be necessary to exclude Wilson disease (24-hour urine copper level), heavy metal intoxication (24-hour urine heavy metal panel), and infectious encephalitis (cerebrospinal fluid polymerase chain reaction for Whipple disease, herpes simplex virus, cytomegalovirus, varicella-zoster virus, and other viruses).

Jakob-Creutzfeldt disease is a relatively common cause of rapidly progressive dementia (see Chapter 32). Family history is important since mutations in PRNP, the gene for the prion protein, account for around 15% of cases. Diffusion-weighted MRI is the most helpful diagnostic tool, classically revealing cortical ribboning (a gyral pattern of hyperintensity) as well as restricted diffusion in the caudate and anterior putamen. Reflecting the high rate of neuronal death, cerebrospinal fluid levels of the intraneuronal proteins tau, 14–3–3, and neuron-specific enolase are often elevated, although this finding is neither sensitive nor specific. An electroencephalogram often shows periodic complexes.
B. Driving and Dementia

It is recommended that any patient with mild dementia or worse should discontinue driving. Most states have laws regulating driving among cognitively impaired individuals, and many require the physician to report the patient’s diagnosis to the public health department or department of motor vehicles. There is no evidence that driving classes help patients with neurodegenerative diseases.

► When to Refer

All patients with new, unexplained cognitive decline should be referred.

► When to Admit

Dementia alone is not an indication for admission, but admission is sometimes necessary when a superimposed delirium poses safety risks at home.

► Clinical Findings

A. Symptoms and Signs

The common initial presentation is weakness, numbness, tingling, or unsteadiness in a limb; spastic paraparesis; retrobulbar optic neuritis; diplopia; dysequilibrium; or a sphincter disturbance such as urinary urgency or hesitancy. Symptoms may disappear after a few days or weeks, although examination often reveals a residual deficit.

Several forms of the disease are recognized. In most patients, there is an interval of months or years after the initial episode before new symptoms develop or the original ones recur (relapsing-remitting disease). Eventually, however, relapses and usually incomplete remissions lead to increasing disability, with weakness, spasticity, and ataxia of the limbs, impaired vision, and urinary incontinence. The findings on examination at this stage commonly include optic atrophy; nystagmus; dysarthria; and pyramidal, sensory, or cerebellar deficits in some or all of the limbs. In some of these patients, the clinical course changes so that a steady deterioration occurs, unrelated to acute relapses (secondary progressive disease). Less common, symptoms are steadily progressive from their onset, and disability develops at a relatively early stage (primary progressive disease). The diagnosis cannot be made with confidence unless the total clinical picture indicates involvement of different parts of the central nervous system at different times. Fatigue is common in all forms of the disease.

A number of factors (eg, infection) may precipitate or trigger exacerbations. Relapses are reduced in pregnancy but are more likely during the 2 or 3 months following pregnancy, possibly because of the increased demands and stresses that occur in the postpartum period.

B. Imaging

MRI of the brain or cervical cord has a major role in demonstrating the presence of multiple lesions. In T1-weighted images, hypointense “black holes” probably represent areas of permanent axonal damage; hyperintense lesions are also found. Gadolinium-enhanced T1-weighted images may highlight areas of inflammation with breakdown of the blood-brain barrier, which helps identify newer lesions. T2-weighted images provide information about disease burden or total number of lesions, which typically appear as areas of high signal intensity. CT scans are less helpful than MRI.

In patients with myelopathy alone and in whom there is no clinical or laboratory evidence of more widespread disease, MRI or myelography may be necessary to exclude a congenital or acquired surgically treatable lesion. The foramen magnum region must be visualized to exclude the possibility of Arnold-Chiari malformation, in which parts of the cerebellum and the lower brainstem are displaced.
into the cervical canal and produce mixed pyramidal and cerebellar deficits in the limbs.

C. Laboratory and Other Studies

A definitive diagnosis can never be based solely on the laboratory findings. If there is clinical evidence of only a single lesion in the central nervous system, multiple sclerosis cannot properly be diagnosed unless it can be shown that other regions are affected subclinically. The electrocerebral responses evoked by monocular visual stimulation with a checkerboard pattern stimulus, by monaural click stimulation, and by electrical stimulation of a sensory or mixed peripheral nerve have been used to detect subclinical involvement of the visual, brainstem auditory, and somatosensory pathways, respectively. Other disorders may also be characterized by multifocal electrophysiologic abnormalities.

There may be mild lymphocytosis or a slightly increased protein concentration in the cerebrospinal fluid, especially soon after an acute relapse. Elevated IgG in cerebrospinal fluid and discrete bands of IgG (oligoclonal bands) are present in many patients. The presence of such bands is not specific, however, since they have been found in a variety of inflammatory neurologic disorders and occasionally in patients with vascular or neoplastic disorders of the nervous system.

D. Diagnosis

Multiple sclerosis should not be diagnosed unless there is evidence that two or more different regions of the central white matter have been affected at different times. A diagnosis of clinically definite disease can be made in patients with a relapsing-remitting course and evidence on examination of at least two lesions involving different regions of the central white matter. The diagnosis is probable in patients with multifocal white matter disease but only one clinical attack, or with a history of at least two clinical attacks but signs of only a single lesion. Imaging may reveal involvement of the nervous system at different times if a gadolinium-enhancing lesion is present at least 3 months after an initial clinical event at a different site than one corresponding to that event or if a new T2 lesion is found at any time compared with a baseline scan obtained at least 30 days after the initial clinical event. Dissemination in space requires three of the following: (1) at least one gadolinium-enhancing lesion or nine T2 hyperintense lesions if there is no enhancing lesion; (2) one or more infratentorial (or spinal cord) lesions; (3) one or more juxtacortical lesions; and (4) at least three periventricular lesions.

In patients with a single clinical event who do not satisfy criteria for multiple sclerosis, a diagnosis of a clinically isolated syndrome (CIS) is made. Such patients are at risk for developing multiple sclerosis and are sometimes offered β-interferon or glatiramer acetate therapy, which may delay progression to clinically definite disease. Follow-up MRI should be considered 6–12 months later to assess for the presence of any new lesion.

Treatment

At least partial recovery from acute exacerbations can reasonably be expected, but further relapses may occur without warning, and there is no means of preventing progression of the disorder. Some disability is likely to result eventually, but about half of all patients are without significant disability even 10 years after onset of symptoms.

Recovery from acute relapses may be hastened by treatment with corticosteroids, but the extent of recovery is unchanged. Intravenous therapy is given first—typically methylprednisolone 1 g daily for 3 days—followed by oral prednisone at 60–80 mg daily for 1 week with a taper over the ensuing 2–3 weeks. Long-term treatment with corticosteroids provides no benefit and does not prevent further relapses.

In patients with relapsing-remitting or secondary progressive disease, indefinite treatment with β-interferon (interferon β-1a 30 mcg intramuscularly once weekly, or 44 mcg subcutaneously three times per week; or interferon β-1b 0.25 mg subcutaneously every other day) or with subcutaneous administration of glatiramer acetate (20 mg daily) reduces the frequency of exacerbations with equal efficacy. Natalizumab, an α4 integrin antagonist that reduces the development of brain lesions in experimental models, reduces the relapse rate when given intravenously once monthly. However, natalizumab treatment is associated with an increased risk of the development of progressive multifocal leukoencephalopathy. Its use is therefore restricted to patients with relapsing-remitting disease who have not responded to other therapies or who have a particularly aggressive initial disease course. It should be used alone and not in combination with β-interferon, glatiramer acetate, or other immune-modifying therapies. Fingolimod (0.5 mg orally daily) reduces the relapse rate in multiple sclerosis, possibly with more efficacy than interferon β-1a. Cladribine and alemtuzumab are being investigated for this indication. Several studies have suggested that immunosuppressive therapy with cyclophosphamide, azathioprine, methotrexate, or mitoxantrone may help arrest the course of secondary progressive multiple sclerosis. The evidence of benefit is incomplete, however. Plasmapheresis is sometimes helpful in patients with severe relapses unresponsive to corticosteroids. Intravenous immunoglobulins (IVIGs) may reduce the clinical attack rate in relapsing-remitting disease, but the available studies are inadequate to permit treatment recommendations. Statins may have immunomodulatory effects, and their possible role in the treatment of multiple sclerosis is being studied.

Symptomatic therapy for spasticity (see below), neurogenic bladder, or fatigue may be required. Fatigue is especially common in multiple sclerosis, and modafinil (200 mg orally every morning) is an effective and FDA-approved therapy for this indication. Dalfampridine (an extended-release formulation of 4-aminopyridine administered as 10 mg orally twice daily) is efficacious at improving timed gait in multiple sclerosis. Depression and even suicidality can occur in multiple sclerosis and may worsen with interferon β-1a therapy; screening and conventional treatment of such symptoms are appropriate.

When to Refer

All patients, but especially those with progressive disease despite standard therapy, should be referred.
**NEUROMYELITIS OPTICA**

This disorder is characterized by optic neuritis and acute myelitis with MRI changes that extend over at least three segments of the spinal cord. An isolated myelitis or optic neuritis may also occur. Previously known as Devic disease and once regarded as a variant of multiple sclerosis, neuromyelitis optica is associated with a specific antibody marker (NMO-IgG) targeting the water channel aquaporin-4. MRI of the brain typically does not show widespread white matter involvement, but such changes do not exclude the diagnosis. Treatment is by long-term immunosuppression. Rituximab may help in reducing the risk of relapses and is undergoing clinical trials; no standard dosing regimen is yet available.

**VITAMIN E DEFICIENCY**

Vitamin E deficiency may produce a disorder somewhat similar to Friedreich ataxia (see below). There is spinocerebellar degeneration involving particularly the posterior columns of the spinal cord and leading to limb ataxia, sensory loss, absent tendon reflexes, slurring of speech and, in some cases, pigmentary retinal degeneration. The disorder may occur as a consequence of malabsorption or on a hereditary basis (eg, abetalipoproteinemia). Treatment is with α-tocopherol acetate as discussed in Chapter 29.

**SPASTICITY**

The term “spasticity” is commonly used for an upper motor neuron deficit, but it properly refers to a velocity-dependent increase in resistance to passive movement that affects different muscles to a different extent, is not uniform in degree throughout the range of a particular movement, and is commonly associated with other features of pyramidal deficit. It is often a major complication of stroke, cerebral or spinal injury, static perinatal encephalopathy, and multiple sclerosis.

Physical therapy with appropriate stretching programs is important during rehabilitation after the development of an upper motor neuron lesion and in subsequent management of the patient. The aim is to prevent joint and muscle contractures and perhaps to modulate spasticity.

Drug management is important also, but treatment may increase functional disability when increased extensor tone is providing additional support for patients with weak legs. Dantrolene weakens muscle contraction by interfering with the role of calcium. It is best avoided in patients with poor respiratory function or severe myocardial disease. Treatment is begun with 2.5 mg once daily, and the daily dose is built up by 2.5 mg increments every 3 days, depending on tolerance, to a maximum of 100 mg four times daily. Side effects include diarrhea, nausea, weakness, hepatic dysfunction (that may rarely be fatal, especially in women older than 35), drowsiness, light-headedness, and hallucinations.

Baclofen is an effective drug for treating spasticity of spinal origin and painful flexor (or extensor) spasms. The maximum recommended daily oral dose is 80 mg; treatment is started with a dose of 5 or 10 mg twice daily orally and then built up gradually. Side effects include gastrointestinal disturbances, lassitude, fatigue, sedation, unsteadiness, confusion, and hallucinations. Diazepam may modify spasticity by its action on spinal interneurons and perhaps also by influencing supraspinal centers, but effective doses often cause intolerable drowsiness and vary with different patients. Tizanidine, a centrally acting α₂-adrenergic agonist, is as effective as these other agents and is probably better tolerated. The daily dose is built up gradually, usually to 8 mg taken three times daily. Side effects include sedation, lassitude, hypotension, and dryness of the mouth.

Intramuscular injection of botulinum toxin has been used to relax targeted muscles.

In patients with severe spasticity that is unresponsive to other therapies and is associated with marked disability, intrathecal injection of phenol or alcohol may be helpful. Surgical options include implantation of an intrathecal baclofen pump, rhizotomy, or neurectomy. Severe contractures may be treated by surgical tendon release.
Spasticity may be exacerbated by decubitus ulcers, urinary or other infections, and nociceptive stimuli.

MYELOPATHIES IN AIDS

A variety of myelopathies may occur in patients with AIDS. These are discussed in Chapter 31.

MYELOPATHY OF HUMAN T CELL LEUKEMIA VIRUS INFECTION

Human T cell leukemia virus (HTLV-1), a human retrovirus, is transmitted by breast-feeding, sexual contact, blood transfusion, and contaminated needles. Most patients are asymptomatic, but after a variable latent period (which may be as long as several years) a myelopathy develops in some instances. The MRI, electrophysiologic, and cerebrospinal fluid findings are similar to those of multiple sclerosis, but HTLV-1 antibodies are present in serum and spinal fluid. There is no specific treatment, but intravenous or oral corticosteroids may help in the initial inflammatory phase of the disease. Prophylactic measures are important. Needles or syringes should not be shared; infected patients should not breastfeed their infants or donate blood, semen, or other tissue. Infected patients should use condoms to prevent sexual transmission.

SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD

Subacute combined degeneration of the spinal cord is due to vitamin B12 deficiency, such as occurs in pernicious anemia. It is characterized by myelopathy with predominant pyramidal and posterior column deficits, sometimes in association with polyneuropathy, mental changes, or optic neuropathy. Megaloblastic anemia may also occur, but this does not parallel the neurologic disorder, and the former may be obscured if folic acid supplements have been taken. Treatment is with vitamin B12. For pernicious anemia, a convenient therapeutic regimen is 100 mg cyanocobalamin intramuscularly daily for 1 week, then weekly for 1 month, and then monthly for the remainder of the patient’s life.

NERVOUS SYSTEM DISORDERS

WERNICKE ENCEPHALOPATHY & KORSAKOFF SYNDROME

Wernicke encephalopathy is characterized by confusion, ataxia, and nystagmus leading to ophthalmoplegia (lateral rectus muscle weakness, conjugate gaze palsy); peripheral neuropathy may also be present. It is due to thiamine deficiency and in the United States occurs most commonly in alcoholics. It may also occur in patients with AIDS or hypoglycemia gravidum, and after surgery for obesity. In suspected cases, thiamine (100 mg) is given intravenously immediately and then intramuscularly on a daily basis until a satisfactory diet can be ensured. Intravenous glucose given before thiamine may precipitate the syndrome or worsen the symptoms. The diagnosis is confirmed by the response in 1 or 2 days to treatment, which must not be delayed while awaiting laboratory confirmation of thiamine deficiency from a blood sample obtained prior to thiamine administration. Korsakoff syndrome occurs in more severe cases; it includes anterograde and retrograde amnesia and sometimes confabulation, and may not be recognized until after the initial delirium has lifted.

STUPOR & COMA

ESSENTIALS OF DIAGNOSIS

- Level of consciousness is depressed.
- Stuporous patients respond only to repeated vigorous stimuli.
- Comatose patients areunarousable and unresponsive.

General Considerations

The patient who is stuporous is unresponsive except when subjected to repeated vigorous stimuli, while the comatose patient is unarousable and unable to respond to external events or inner needs, although reflex movements and posturing may be present.

Coma is a major complication of serious central nervous system disorders. It can result from seizures, hypothermia, metabolic disturbances, or structural lesions causing bilateral cerebral hemispheric dysfunction or a disturbance of the brainstem reticular activating system. A mass lesion involving one cerebral hemisphere may cause coma by compression of the brainstem. All comatose patients should be admitted to hospital and referred to a neurologist or neurosurgeon.

Assessment & Emergency Measures

The diagnostic workup of the comatose patient must proceed concomitantly with management. Supportive therapy...
for respiration or blood pressure is initiated; in hypo-
thermia, all vital signs may be absent and all such patients
should be rewarmed before the prognosis is assessed.

The patient can be positioned on one side with the neck
partly extended, dentures removed, and secretions cleared
by suction; if necessary, the patency of the airways is main-
tained with an oropharyngeal airway. Blood is drawn for
serum glucose, electrolyte, and calcium levels; arterial
blood gases; liver and kidney function tests; and toxicologic
studies as indicated. Dextrose 50% (25 g), naloxone (0.4–
1.2 mg), and thiamine (100 mg) are given intravenously
without delay.

Further details are then obtained from attendants of the
patient’s medical history, the circumstances surrounding
the onset of coma, and the time course of subsequent
events. Abrupt onset of coma suggests subarachnoid hem-
orrhage, brainstem stroke, or intracerebral hemorrhage,
whereas a slower onset and progression occur with other
structural or mass lesions. Urgent noncontrast CT scan-
ing of the head is appropriate if it can be obtained directly
from the emergency department, in order to identify
intracranial hemorrhage, brain herniation, or other struc-
tural lesion that may require immediate neurosurgical
intervention. A metabolic cause is likely with a preceding
intoxicated state or agitated delirium. On examination,
attention is paid to the behavioral response to painful
stimuli, the pupils and their response to light, the position
of the eyes and their movement in response to passive
movement of the head and ice-water caloric stimulation,
and the respiratory pattern.

A. Response to Painful Stimuli

Purposive limb withdrawal from painful stimuli implies
that sensory pathways from and motor pathways to the
stimulated limb are functionally intact. Unilateral absence
of responses despite application of stimuli to both sides of
the body in turn implies a corticospinal lesion; bilateral
absence of responsiveness suggests brainstem involvement,
bilateral pyramidal tract lesions, or psychogenic unrespon-
siveness. Inappropriate responses may also occur.
Decorticate posturing may occur with lesions of the inter-
 nal capsule and rostral cerebral peduncle, decerebrate
posturing with dysfunction or destruction of the midbrain
and rostral pons, and decerebrate posturing in the arms
accompanied by flaccidity or slight flexor responses in the
legs in patients with extensive brainstem damage extending
down to the pons at the trigeminal level.

B. Ocular Findings

1. Pupils—Hypothalamic disease processes may lead to
unilateral Horner syndrome, while bilateral diencephalic
involvement or destructive pontine lesions may lead to
small but reactive pupils. Ipsilateral pupillary dilation with
no direct or consensual response to light occurs with com-
pression of the third cranial nerve, eg, with uncal hernia-
tion. The pupils are slightly smaller than normal but
responsive to light in many metabolic encephalopathies;
however, they may be fixed and dilated following overdosage
with atropine or scopolamine, and pinpoint (but respon-
sive) with opioids. Pupillary dilation for several hours
following cardiopulmonary arrest implies a poor
prognosis.

2. Eye movements—Conjugate deviation of the eyes to
the side suggests the presence of an ipsilateral hemispheric
lesion or a contralateral pontine lesion. A mesencephalic
lesion leads to downward conjugate deviation. Dysconjugate
ocular deviation in coma implies a structural brainstem
lesion unless there was preexisting strabismus.

The oculomotor responses to passive head turning and to
caloric stimulation relate to each other and provide
complementary information. In response to brisk rotation
of the head from side to side and to flexion and extension
of the head, normally conscious patients with open eyes do
not exhibit contraversive conjugate eye deviation (doll’s-
head eye response) unless there is voluntary visual fixation
or bilateral frontal pathologic. With cortical depression in
lightly comatose patients, a brisk doll’s-head eye response
is seen. With brainstem lesions, this oculocephalic reflex
becomes impaired or lost, depending on the site of the
lesion.

The oculovestibular reflex is tested by caloric stimula-
tion using irrigation with ice water. In normal subjects,
jerk nystagmus is elicited for about 2 or 3 minutes, with
the slow component toward the irrigated ear. In uncon-
scious patients with an intact brainstem, the fast compo-
nent of the nystagmus disappears, so that the eyes
tonically deviate toward the irrigated side for 2–3 minutes
before returning to their original position. With impair-
ment of brainstem function, the response becomes per-
verted and finally disappears. In metabolic coma, ocu-
locephalic and oculovestibular reflex responses are
preserved, at least initially.

C. Respiratory Patterns

Diseases causing coma may lead to respiratory abnormali-
 ties. Cheyne-Stokes respiration (in which episodes of deep
breathing alternate with periods of apnea) may occur with
bihemispheric or diencephalic disease or in metabolic dis-
orders. Central neurogenic hyperventilation occurs with
lesions of the brainstem tegmentum; apneustic breathing
(in which there are prominent end-inspiratory pauses)
suggests damage at the pontine level (eg, due to basilar
artery occlusion); and atactic breathing (a completely
irregular pattern of breathing with deep and shallow
breaths occurring randomly) is associated with lesions of
the lower pontine tegmentum and medulla.

1. Stupor & Coma Due to Structural Lesions

Supratentorial mass lesions tend to affect brain function in
an orderly way. There may initially be signs of hemispheric
dysfunction, such as hemiparesis. As coma develops and
deepens, cerebral function becomes progressively dis-
turbed, producing a predictable progression of neurologic
signs that suggest rostrocaudal deterioration.

Thus, as a supratentorial mass lesion begins to impair
the diencephalon, the patient becomes drowsy, then
stuporous, and finally comatose. There may be Cheyne-Stokes respiration; small but reactive pupils; doll's-head eye responses with side-to-side head movements but sometimes an impairment of reflex upward gaze with brisk flexion of the head; tonic ipsilateral deviation of the eyes in response to vestibular stimulation with cold water; and initially a positive response to pain but subsequently only decorticate posturing. With further progression, midbrain failure occurs. Motor dysfunction progresses from decorticate to bilateral decerebrate posturing in response to painful stimuli; Cheyne-Stokes respiration is gradually replaced by sustained central hyperventilation; the pupils become middle-sized and fixed; and the oculofacial and oculovestibular reflex responses become impaired, perverted, or lost. As the pons and then the medulla fail, the pupils remain unresponsive; oculovestibular responses are unobtainable; respiration is rapid and shallow; and painful stimuli may lead only to flexor responses in the legs. Finally, respiration becomes irregular and stops, the pupils often then dilating widely.

In contrast, a subtentorial (ie, brainstem) lesion may lead to an early, sometimes abrupt disturbance of consciousness without any orderly rostrocaudal progression of neurologic signs. Compressive lesions of the brainstem, especially cerebellar hemorrhage, may be clinically indistinguishable from intraparenchymal processes.

A structural lesion is suspected if the findings suggest focality. In such circumstances, a CT scan should be performed before, or instead of, a lumbar puncture in order to avoid any risk of cerebral herniation. Further management is of the causal lesion and is considered separately under the individual disorders.

In some cases of traumatic brain injury, swelling may be diffuse rather than focal. Decompressive craniectomy may reduce otherwise refractory intracranial hypertension but does not improve neurologic outcome. Hypothermic therapy is controversial.

2. Stupor & Coma Due to Metabolic Disturbances

Patients with a metabolic cause of coma generally have signs of patchy, diffuse, and symmetric neurologic involvement that cannot be explained by loss of function at any single level or in a sequential manner, although focal or lateralized deficits may occur in hypoglycemia. Moreover, pupillary reactivity is usually preserved, while other brainstem functions are often grossly impaired. Comatose patients with meningitis, encephalitis, or subarachnoid hemorrhage may also exhibit little in the way of focal neurologic signs, however, and clinical evidence of meningeal irritation is sometimes very subtle in comatose patients. Examination of the cerebrospinal fluid in such patients is essential to establish the correct diagnosis.

In patients with coma due to cerebral ischemia and hypoxia, the absence of pupillary light reflexes at the time of initial examination indicates that there is little chance of regaining independence; by contrast, preserved pupillary light responses, the development of spontaneous eye movements (roving, conjugate, or better), and extensor flexor, or withdrawal responses to pain at this early stage imply a relatively good prognosis.

Treatment of metabolic encephalopathy is of the underlying disturbance and is considered in other chapters. If the cause of the encephalopathy is obscure, all drugs except essential ones may have to be withdrawn in case they are responsible for the altered mental status.

3. Brain Death

The definition of brain death is controversial, and diagnostic criteria have been published by many different professional organizations. In order to establish brain death, the irreversibly comatose patient must be shown to have lost all brainstem reflex responses, including the pupillary, corneal, oculovestibular, oculocephalic, oropharyngeal, and respiratory reflexes, and should have been in this condition for at least 6 hours. Spinal reflex movements do not exclude the diagnosis, but ongoing seizure activity or decerebrate or decorticate posturing is not consistent with brain death. The apnea test (presence or absence of spontaneous respiratory activity at a Paco2 of at least 60 mm Hg) serves to determine whether the patient is capable of respiratory activity.

Reversible coma simulating brain death may be seen with hypothermia (temperature <32°C) and overdosage with central nervous system depressant drugs, and these conditions must be excluded. Certain ancillary tests may assist the determination of brain death but are not essential. An isoelectric electroencephalogram, when the recording is made according to the recommendations of the American Electroencephalographic Society, may help in confirming the diagnosis. Alternatively, the demonstration of an absent cerebral circulation by intravenous radioisotope cerebral angiography or by four-vessel contrast cerebral angiography is confirmatory.

4. Persistent Vegetative State

Patients with severe bilateral hemispheric disease may show some improvement from an initially comatose state, so that, after a variable interval, they appear to be awake but lie motionless and without evidence of awareness or higher mental activity. This persistent vegetative state has been variously referred to as akinetic mutism, apallic state, or coma vigil. Most patients in this persistent vegetative state will die in months or years, but partial recovery has occasionally occurred and in rare instances has been sufficient to permit communication or even independent living.

5. Minimally Conscious State

In this state, patients exhibit inconsistent evidence of consciousness. There is some degree of functional recovery of behaviors suggesting self- or environmental awareness, such as basic verbalization or context-appropriate gestures, emotional responses (eg, smiling) to emotional but not neutral stimuli, or purposive responses to environmental stimuli (eg, a finger movement or eye blink apparently to command). Further improvement is manifest by the restoration of communication with the patient. The minimally conscious state may be temporary or permanent. Little information is available about its natural history or long-term outlook, which reflect the underlying cause. The likelihood of useful functional recovery diminishes with time; after 12 months, patients are likely to remain severely disabled and without a reliable means of communication. Prognostication is difficult.

6. Locked-In Syndrome (De-efferented State)

Acute destructive lesions (eg, infarction, hemorrhage, demyelination, encephalitis) involving the ventral pons and sparing the tegmentum may lead to a mute, quadriparetic but conscious state in which the patient is capable of blinking and of voluntary eye movement in the vertical plane, with preserved pupillary responses to light. Such a patient can mistakenly be regarded as comatose. Physicians should recognize that “locked-in” individuals are fully aware of their surroundings. The prognosis is usually poor, but recovery has occasionally been reported in some cases, including resumption of independent daily life.

HEAD INJURY

Trauma is the most common cause of death in young people, and head injury accounts for almost half of these trauma-related deaths. The incidence of head injury can be reduced by, for example, using bicycle helmets and protective equipment in sports.

The prognosis following head injury depends on the site and severity of brain damage. Some guide to prognosis is provided by the mental status, since loss of consciousness implies a worse prognosis than otherwise. Similarly, the degree of retrograde and posttraumatic amnesia provides an indication of the severity of injury and thus of the prognosis. Absence of skull fracture does not exclude the possibility of severe head injury. During the physical examination, special attention should be given to the level of consciousness and extent of any brainstem dysfunction.

Note: Patients (especially elderly, >65 years) who are intoxicated with drugs or alcohol or have evidence of soft-tissue injury above the clavicles following head injury should be admitted to the hospital for observation, as should patients with recurrent vomiting, persistent anterograde amnesia, retrograde amnesia for more than 30 minutes, focal neurologic deficits, lethargy, or skull fractures. If admission is declined, responsible family members should be given clear instructions about the need for, and manner of, checking on them at regular (hourly) intervals and for obtaining additional medical help if necessary.

Skull radiographs or CT scans may provide evidence of fractures. Because injury to the spine may have accompanied head trauma, cervical spine radiographs (especially in the lateral projection) should always be obtained in comatose patients and in patients with severe neck pain or a deficit possibly related to cord compression.

CT scanning has an important role in demonstrating intracranial hemorrhage and may also provide evidence of cerebral edema and displacement of midline structures.

1. Cerebral Injuries

These are summarized in Table 24–8. Increased intracranial pressure may result from ventilatory obstruction, abnormal neck position, seizures, dilutional hyponatremia, or cerebral edema; an intracranial hematoma requiring surgical evacuation may also be responsible. Other measures that may be necessary to reduce intracranial pressure include induced hyperventilation, intravenous mannitol infusion, and intravenous furosemide; corticosteroids provide no benefit in this context. Overall, treatment is mainly supportive. The role of induced hypothermia in reducing long-term neurologic deficits is currently under investigation.

2. Scalp Injuries & Skull Fractures

Scalp lacerations and depressed or compound depressed skull fractures should be treated surgically as appropriate. Simple skull fractures require no specific treatment.

The clinical signs of basilar skull fracture include bruising about the orbit (raccoon sign), blood in the external auditory meatus (Battle sign), and leakage of cerebrospinal fluid (which can be identified by its glucose content) from the ear or nose. Cranial nerve palsies (involving especially the first, second, third, fourth, fifth, seventh, and eighth nerves in any combination) may also occur. If there is any leakage of cerebrospinal fluid, conservative treatment, with elevation of the head, restriction of fluids, and administration of acetazolamide (250 mg four times daily), is often helpful; but if the leak continues for more than a few days, lumbar subarachnoid drainage may be necessary.
Normal-pressure hydrocephalus may follow head injury, subarachnoid hemorrhage, or meningoencephalitis. Other late complications of head injury include posttraumatic seizure disorder, headache, vertigo, and hyposmia.

When to Refer

- Patients with focal neurologic deficits, altered consciousness, or skull fracture.
- Patients with late complications of head injury, eg, posttraumatic seizure disorder or normal pressure hydrocephalus.

When to Admit

- Patients (especially elderly, >65 years) who are intoxicated with drugs or alcohol or have evidence of soft-tissue injury above the clavicles should be admitted for observation.
- Patients with recurrent vomiting, focal neurologic deficits, persistent anterograde amnesia, retrograde amnesia for more than 30 minutes, altered consciousness, or skull fracture.
- Patients with acute epidural, subdural, or cerebral hematoma.
- Patients requiring shunt placement for normal pressure hydrocephalus.
SPINAL TRAUMA

ESSENTIALS OF DIAGNOSIS

- History of preceding trauma.
- Development of acute neurologic deficit.
- Signs of myelopathy on examination.

General Considerations

While spinal cord damage may result from whiplash injury, severe injury usually relates to fracture-dislocation causing compression or angular deformity of the cord either cervically or in the lower thoracic and upper lumbar regions. Extreme hypotension following injury may also lead to cord infarction.

Clinical Findings

Total cord transaction results in immediate flaccid paralysis and loss of sensation below the level of the lesion. Reflex activity is lost for a variable period, and there is urinary and fecal retention. As reflex function returns over the following days and weeks, spastic paraplegia or quadriplegia develops, with hyperreflexia and extensor plantar responses, but a flaccid atrophic (lower motor neuron) paralysis may be found depending on the segments of the cord that are affected. The bladder and bowels also regain some reflex function, permitting urine and feces to be expelled at intervals. As spasticity increases, flexor or extensor spasms (or both) of the legs become troublesome, especially if the patient develops bed sores or a urinary tract infection. Paraplegia with the legs in flexion or extension may eventually result.

With lesser degrees of injury, patients may be left with mild limb weakness, distal sensory disturbance, or both. Sphincter function may also be impaired, urinary urgency and urgency incontinence being especially common. More particularly, a unilateral cord lesion leads to an ipsilateral motor disturbance with accompanying impairment of proprioception and contralateral loss of pain and temperature appreciation below the lesion (Brown-Séquard syndrome). A central cord syndrome may lead to a lower motor neuron deficit and loss of pain and temperature appreciation, with sparing of posterior column functions. A radicular deficit may occur at the level of the injury—or, if the cauda equina is involved, there may be evidence of disturbed function in several lumbosacral roots.

Treatment

Treatment of the injury consists of immobilization and—if there is cord compression—early decompressive laminectomy and fusion (within 24 hours). Early treatment with high doses of corticosteroids (eg, methylprednisolone, 30 mg/kg by intravenous bolus, followed by 5.4 mg/kg/h for 23 hours) may improve neurologic recovery if commenced within 8 hours after injury; the findings from various studies are conflicting, however, and evaluation of the published evidence suggest that significant benefit is unlikely. Anatomic realignment of the spinal cord by traction and other orthopedic procedures is important. Subsequent care of the residual neurologic deficit—paraplegia or quadriplegia—requires treatment of spasticity and care of the skin, bladder, and bowels.

When to Refer

All patients with focal neurologic deficits should be referred.

When to Admit

- Patients with neurologic deficits.
- Patients with spinal cord injury, compression, or acute epidural or subdural hematoma.
- Patients with vertebral fracture-dislocation likely to compress the cord.

Syringomyelia

Destruction or degeneration of gray and white matter adjacent to the central canal of the cervical spinal cord leads to cavitation and accumulation of fluid within the spinal cord. The precise pathogenesis is unclear, but many cases are associated with Arnold-Chiari malformation, in which there is displacement of the cerebellar tonsils, medulla, and fourth ventricle into the spinal canal, sometimes with accompanying meningomyelocele. In such circumstances, the cord cavity connects with and may merely represent a dilated central canal. In other cases, the cause of cavitation is less clear. There is a characteristic clinical picture, with segmental atrophy, areflexia and loss of pain and temperature appreciation in a “cape” distribution, owing to the destruction of fibers crossing in front of the central canal in the mid-cervical spinal cord. Thoracic kyphoscoliosis is usually present. With progression, involvement of the long motor and sensory tracts occurs as well, so that a pyramidal and sensory deficit develops in the legs. Upward extension...
of the cavitation (syringobulbia) leads to dysfunction of the lower brainstem and thus to bulbar palsy, nystagmus, and sensory impairment over one or both sides of the face.

Syringomyelia, ie, cord cavitation, may also occur in association with an intramedullary tumor or following severe cord injury, and the cavity then does not communicate with the central canal.

In patients with Arnold-Chiari malformation, CT scans reveal a small posterior fossa and enlargement of the foramen magnum, along with other associated skeletal abnormalities at the base of the skull and upper cervical spine. MRI reveals the syrinx as well as the characteristic findings of the Arnold-Chiari malformation, including the caudal displacement of the fourth ventricle and herniation of the cerebellar tonsils through the foramen magnum. Focal cord enlargement is found at myelography or by MRI in patients with cavitation related to past injury or intramedullary neoplasms.

Treatment of Arnold-Chiari malformation with associated syringomyelia is by suboccipital craniectomy and upper cervical laminectomy, with the aim of decompressing the malformation at the foramen magnum. The cord cavity should be drained, and if necessary an outlet for the fourth ventricle can be made. In cavitation associated with intra-medullary tumor, treatment is surgical, but radiation therapy may be necessary if complete removal is not possible. Posttraumatic syringomyelia is also treated surgically if it leads to increasing neurologic deficits or to intolerable pain.

**DEGENERATIVE MOTOR NEURON DISEASES**

**ESSENTIALS OF DIAGNOSIS**

- Weakness.
- No sensory loss or sphincter disturbance.
- Progressive course.
- No identifiable underlying cause other than genetic basis in familial cases.

**General Considerations**

This group of degenerative disorders is characterized clinically by weakness and variable wasting of affected muscles, without accompanying sensory changes.

Motor neuron disease in adults generally commences between 30 and 60 years of age. There is degeneration of the anterior horn cells in the spinal cord, the motor nuclei of the lower cranial nerves, and the corticospinal and corticobulbar pathways. The disorder is usually sporadic, but familial cases may occur and several genetic mutations or loci have been identified. Cigarette smoking may be one risk factor.

**Classification**

Five varieties have been distinguished on clinical grounds.

**A. Progressive Bulbar Palsy**

Bulbar involvement predominates owing to disease processes affecting primarily the motor nuclei of the cranial nerves.

**B. Pseudobulbar Palsy**

Bulbar involvement predominates in this variety also, but it is due to bilateral corticobulbar disease and thus reflects upper motor neuron dysfunction. There may be a “pseudobulbar affect,” with uncontrollable episodes of laughing or crying to stimuli that would not normally have elicited such marked reactions.

**C. Progressive Spinal Muscular Atrophy**

This is characterized primarily by a lower motor neuron deficit in the limbs due to degeneration of the anterior horn cells in the spinal cord.

**D. Primary Lateral Sclerosis**

There is a purely upper motor neuron deficit in the limbs.

**E. Amyotrophic Lateral Sclerosis**

A mixed upper and lower motor neuron deficit is found in the limbs. This disorder is sometimes associated with cognitive decline (in a pattern consistent with frontotemporal dementia), a pseudobulbar affect, or parkinsonism.

**Clinical Findings**

**A. Symptoms and Signs**

Difficulty in swallowing, chewing, coughing, breathing, and talking (dysarthria) occur with bulbar involvement. In progressive bulbar palsy, there is drooping of the palate; a depressed gag reflex; pooling of saliva in the pharynx; a weak cough; and a wasted, fasciculating tongue. In pseudobulbar palsy, the tongue is contracted and spastic and cannot be moved rapidly from side to side. Limb involvement is characterized by motor disturbances (weakness, stiffness, wasting, fasciculations) reflecting lower or upper motor neuron dysfunction; there are no objective changes on sensory examination, although there may be vague sensory complaints. The sphincters are generally spared. Cognitive changes or pseudobulbar affect may be present. The disorder is progressive, and amyotrophic lateral sclerosis is usually fatal within 3–5 years; death usually results from pulmonary infections. Patients with bulbar involvement generally have the poorest prognosis, while patients with primary lateral sclerosis often have a longer survival despite profound quadriplegia and spasticity.

**B. Laboratory and Other Studies**

Electromyography may show changes of chronic partial denervation, with abnormal spontaneous activity in the resting muscle and a reduction in the number of motor neurons.
units under voluntary control. In patients with suspected spinal muscular atrophy or amyotrophic lateral sclerosis, the diagnosis should not be made with confidence unless such changes are found in at least three spinal regions (cervical, thoracic, lumbosacral) or two spinal regions and the bulbar musculature. Motor conduction velocity is usually normal but may be slightly reduced, and sensory conduction studies are also normal. Biopsy of a wasted muscle shows the histologic changes of denervation. The serum creatine kinase may be slightly elevated but never reaches the extremely high values seen in some of the muscular dystrophies. The cerebrospinal fluid is normal.

Approximately 10% of cases of amyotrophic lateral sclerosis are familial and have been associated with mutations at several different genetic loci. The spinal muscular atrophies (SMAs) are inherited syndromes caused most often by mutations of the survival motor neuron (SMN) gene on chromosome 5. Different mutations result in more or less severe disruptions of the protein, resulting in an age of onset that ranges from infancy (SMA type I; Werdnig-Hoffmann disease), to early (type II) or late childhood (type III; Kugelberg-Welander syndrome), to adulthood (type IV). X-linked bulbospinal neuronopathy (Kennedy syndrome) is associated with an expanded trinucleotide repeat sequence on the androgen receptor gene and carries a more benign prognosis than other forms of motor neuron disease. There have been recent reports of juvenile spinal muscular atrophy due to hexosaminidase deficiency, with abnormal findings on rectal biopsy and reduced hexosaminidase A in serum and leukocytes. Pure motor syndromes resembling motor neuron disease may also occur in association with monoclonal gammopathy or multifocal motor neuropathies with conduction block. A motor neuronopathy may also develop in Hodgkin disease and has a relatively benign prognosis. Infective anterior horn cell diseases (polio virus or West Nile virus infection) can generally be distinguished by the acute onset and monophasic course of the illness, as discussed in Chapter 32.

**Treatment**

Riluzole, 50 mg orally twice daily, which reduces the presynaptic release of glutamate, may slow progression of amyotrophic lateral sclerosis. There is otherwise no specific treatment except in patients with gammopathy, in whom plasmapheresis and immunosuppression may lead to improvement. Therapeutic trials of various neurotrophic factors and other agents to slow disease progression have yielded generally disappointing results. Symptomatic and supportive measures may include prescription of anticholinergic drugs (such as trihexyphenidyl, amitriptyline, or atropine) or use of a portable suction machine if drooling is troublesome, braces or a walker to improve mobility, and physical therapy to prevent contractures. Behavioral modification (eg, exercising facial muscles and encouraging frequent swallowing) or over-the-counter decongestants may also help mild drooling. Spasticity may be helped by baclofen or diazepam. A semiliquid diet or nasogastric tube feeding may be needed if dysphagia is severe. Gastrostomy or cricopharyngomyotomy is sometimes resorted to in extreme cases of predominant bulbar involvement, and tracheostomy may be necessary if respiratory muscles are severely affected; however, in the terminal stages of these disorders, the aim of treatment should be to keep patients as comfortable as possible. Information on palliative care is provided in Chapter 5.

**When to Refer**

All patients (to exclude other treatable causes of symptoms and signs) should be referred.

**When to Admit**

Patients should be admitted during the terminal stages of the disorders for palliative care.

**PERIPHERAL NEUROPATHIES**

Peripheral neuropathies can be categorized on the basis of the structure primarily affected. The predominant pathologic feature may be axonal degeneration (axonal or neuronal neuropathies) or paradorsal or segmental demyelination. The distinction may be possible on the basis of neurophysiologic findings. Motor and sensory conduction velocity can be measured in accessible segments of peripheral nerves. In axonal neuropathies, conduction velocity is normal or reduced only mildly and needle electromyography provides evidence of denervation in affected muscles. In demyelinating neuropathies, conduction may be slowed considerably in affected fibers, and in more severe cases, conduction is blocked completely, without accompanying electromyographic signs of denervation.

Nerves may be injured or compressed by neighboring anatomic structures at any point along their course. Common mononeuropathies of this sort are considered below. They lead to a sensory, motor, or mixed deficit that is restricted to the territory of the affected nerve. A similar clinical disturbance is produced by peripheral nerve tumors, but these are rare except in patients with neurofibromatosis type 1. Multiple mononeuropathies suggest a patchy multifocal disease process such as vasculopathy (eg, diabetes, arteritis), an infiltrative process (eg, leprosy, sarcoidosis), radiation damage, or an immunologic disorder (eg, brachial plexopathy). Diffuse polineuropathies lead to a symmetric sensory, motor, or mixed deficit, often most marked distally. They include the hereditary, metabolic,
and toxic disorders; idiopathic inflammatory polyneuropathy (Guillain-Barré syndrome); and the peripheral neuropathies that may occur as a nonmetastatic complication of malignant diseases. Involvement of motor fibers leads to flaccid weakness that is most marked distally; dysfunction of sensory fibers causes impaired sensory perception. Tendon reflexes are depressed or absent. Paresthesias, pain, and muscle tenderness may also occur.

**POLYNEUROPATHIES & MONONEURITIS MULTIPLEX**

**ESSENTIALS OF DIAGNOSIS**

- Weakness, sensory disturbances, or both in the extremities.
- Pain sometimes common.
- Depressed or absent tendon reflexes.
- May be family history of neuropathy.
- May be history of systemic illness or toxic exposure.

The cause of polyneuropathy or mononeuritis multiplex is suggested by the history, mode of onset, and predominant clinical manifestations. Laboratory workup includes a complete blood count and erythrocyte sedimentation rate, serum protein electrophoresis, and immunophenotyping, determination of plasma urea and electrolytes, liver and thyroid function tests, tests for rheumatoid factor and antinuclear antibody, HBsAg determination, a serologic test for syphilis, fasting blood glucose level, urinary heavy metal levels, cerebrospinal fluid examination, and chest radiography. These tests should be ordered selectively, as guided by symptoms and signs. Measurement of nerve conduction velocity is important in confirming the peripheral nerve origin of symptoms and providing a means of following clinical changes, as well as indicating the likely disease process (ie, axonal or demyelinating neuropathy). Cutaneous nerve biopsy may help establish a precise diagnosis (eg, polyarteritis, amyloidosis). In about half of cases, no specific cause can be established; of these, slightly less than half are subsequently found to be familial.

Treatment is of the underlying cause, when feasible, and is discussed below under the individual disorders. Physical therapy helps prevent contractures, and splints can maintain a weak extremity in a position of useful function. Anesthetic extremities must be protected from injury. To guard against burns, patients should check the temperature of water and hot surfaces with a portion of skin having normal sensation, measure water temperature with a thermometer, and use cold water for washing or lower the temperature setting of their hot-water heaters. Shoes should be examined frequently during the day for grit or foreign objects in order to prevent pressure lesions.

Patients with polyneuropathies or mononeuritis multiplex are subject to additional nerve injury at pressure points and should therefore avoid such behavior as leaning on elbows or sitting with crossed legs for lengthy periods.

Neuropathic, burning pain is sometimes troublesome and may respond to simple analgesics, such as aspirin or nonsteroidal anti-inflammatory agents, and to gabapentin (300 mg orally three times daily, titrated up to a maximum of 1200 mg orally three times daily as necessary). Duloxetine (60 mg orally daily) or venlafaxine (start 37.5 mg orally twice daily, and titrate up to 75 mg orally two to three times daily) may be helpful, especially in painful diabetic neuropathy. Opioids may be necessary for severe hyperpathia or pain induced by minimal stimuli, but their use should be avoided as much as possible. The use of a frame or cradle to reduce contact with bedclothes may be helpful. Many patients experience episodic stabbing pains, which may respond to gabapentin, pregabalin (100 mg orally three times daily), carbamazepine (start 100 mg orally twice daily, and titrate up to 400 mg orally twice daily), or tricyclic antidepressants (eg, amitriptyline 10–150 mg orally at bedtime daily).

Symptoms of autonomic dysfunction are occasionally troublesome. Postural hypotension is often helped by wearing waist-high elastic stockings and sleeping in a semierect position at night. Fludrocortisone reduces postural hypotension, but doses as high as 1 mg/d are sometimes necessary in diabetics and may lead to recumbent hypertension. Midodrine, an α-agonist, is sometimes helpful in a dose of 2.5–10 mg three times daily. Erectile dysfunction and diarrhea are difficult to treat; a flaccid neuropathic bladder may respond to parasympathomimetic drugs such as bethanechol chloride, 10–50 mg three or four times daily.

Kanji JN et al. Does this patient with diabetes have large-fiber peripheral neuropathy? JAMA. 2010 Apr 21;303(15):1526–32. [PMID: 20407062]

1. Inherited Neuropathies

A. Charcot-Marie-Tooth Disease (HMSN Type I, II)

Several distinct varieties of Charcot-Marie-Tooth disease can be recognized. There is usually an autosomal dominant mode of inheritance, but occasional cases occur on a sporadic, recessive, or X-linked basis. The responsible gene is commonly located on the short arm of chromosome 17 and less often shows linkage to chromosome 1 or the X chromosome. It has also been linked to several other chromosomes, emphasizing the genetic heterogeneity of the disorder. Clinical presentation may be with foot deformities or gait disturbances in childhood or early adult life. Slow progression leads to the typical features of polyneuropathy, with distal weakness and wasting that begin in the legs, a variable amount of distal sensory loss, and depressed or absent tendon reflexes. Tremor is a conspicuous feature.
in some instances. Electrodiagnostic studies show a marked reduction in motor and sensory conduction velocity (hereditary motor and sensory neuropathy [HMSN] type I).

In other instances (HMSN type II), motor conduction velocity is normal or only slightly reduced, sensory nerve action potentials may be absent, and signs of chronic partial denervation are found in affected muscles electromyographically. The predominant pathologic change is axonal loss rather than segmental demyelination.

A similar disorder may occur in patients with progressive distal spinal muscular atrophy, but there is no sensory loss; electrophysiologic investigation reveals that motor conduction velocity is normal or only slightly reduced, and nerve action potentials are normal.

B. Dejerine-Sottas Disease (HMSN Type III)
The disorder may occur on a sporadic, autosomal dominant or, less commonly, autosomal recessive basis. Onset in infancy or childhood leads to a progressive motor and sensory polyneuropathy with weakness, ataxia, sensory loss, and depressed or absent tendon reflexes. The peripheral nerves may be palpably enlarged and are characterized pathologically by segmental demyelination, Schwann cell hyperplasia, and thin myelin sheaths. Electrophysiologically, there is slowing of conduction, and sensory action potentials may be unrecordable.

C. Friedreich Ataxia
This disorder, the only known autosomal recessive trinucleotide repeat disease, is caused by expansion of a poly-GAA locus in the gene for frataxin on chromosome 9, leading to symptoms in childhood or early adult life. The gait becomes ataxic, the hands become clumsy, and other signs of cerebellar dysfunction develop accompanied by weakness of the legs and extensor plantar responses. Involvement of peripheral sensory fibers leads to sensory disturbances in the limbs and depressed tendon reflexes. There is bilateral pes cavus. Pathologically, there is a marked loss of cells in the posterior root ganglia and degeneration of peripheral sensory fibers. In the central nervous system, changes are conspicuous in the posterior and lateral columns of the cord. Electrophysiologically, conduction velocity in motor fibers is normal or only mildly reduced, but sensory action potentials are small or absent. Cardiac disease is the most common cause of death.

In the differential diagnosis for Friedreich ataxia are other spinocerebellar ataxias, a growing group of at least 29 inherited disorders, each involving a different identified gene. These heterogeneous disorders, which frequently (but not exclusively) exhibit an autosomal dominant inheritance pattern and poly-CAG expansion of the affected gene, typically cause cerebellar ataxia and varying combinations of other symptoms (such as peripheral neuropathy, ophthalmoparesis, dysarthria, and pyramidal and extrapyramidal signs).

D. Refsum Disease (HMSN Type IV)
This autosomal recessive disorder is due to a disturbance in phytanic acid metabolism. Clinically, pigmentary retinal degeneration is accompanied by progressive sensorimotor polyneuropathy and cerebellar signs. Auditory dysfunction, cardiomyopathy, and cutaneous manifestations may also occur. Motor and sensory conduction velocity are reduced, often markedly, and there may be electromyographic evidence of denervation in affected muscles. Dietary restriction of phytanic acid and its precursors may be helpful therapeutically. Plasmapheresis to reduce stored phytanic acid may help at the initiation of treatment.

E. Porphyria
Peripheral nerve involvement may occur during acute attacks in both variegate porphyria and acute intermittent porphyria. Motor symptoms usually occur first, and weakness is often most marked proximally and in the upper limbs rather than the lower. Sensory symptoms and signs may be proximal or distal in distribution. Autonomic involvement is sometimes pronounced. The electrophysiologic findings are in keeping with the results of neuropathologic studies suggesting that the neuropathy is axonal in type. Hematin (4 mg/kg intravenously over 15 minutes once or twice daily) may lead to rapid improvement. A high-carbohydrate diet and, in severe cases, intravenous glucose or levulose may also be helpful. Propranolol (up to 100 mg orally every 4 hours) may control tachycardia and hypertension in acute attacks.

2. Neuropathies Associated with Systemic & Metabolic Disorders
A. Diabetes Mellitus
In this disorder, involvement of the peripheral nervous system may lead to symmetric sensory or mixed polyneuropathy, asymmetric motor radiculoneuropathy orplexopathy (diabetic amyotrophy), thoracoabdominal radiculopathy, autonomic neuropathy, or isolated lesions of individual nerves. These may occur singly or in any combination and are discussed in Chapter 27.

B. Uremia
Uremia may lead to a symmetric sensorimotor polyneuropathy that tends to affect the lower limbs more than the upper limbs and is more marked distally than proximally (see Chapter 22). The diagnosis can be confirmed electrophysiologically, for motor and sensory conduction velocity is moderately reduced. The neuropathy improves both clinically and electrophysiologically with kidney transplantation and to a lesser extent with chronic dialysis.
C. Alcoholism and Nutritional Deficiency

Many alcoholics have an axonal distal sensorimotor polyneuropathy that is frequently accompanied by painful cramps, muscle tenderness, and painful paresthesias and is often more marked in the legs than in the arms. Symptoms of autonomic dysfunction may also be conspicuous. Motor and sensory conduction velocity may be slightly reduced, even in subclinical cases, but gross slowing of conduction is uncommon. A similar distal sensorimotor polyneuropathy is a well-recognized feature of beriberi (thiamine deficiency). In vitamin B₁₂ deficiency, distal sensory polyneuropathy may develop but is usually overshadowed by central nervous system manifestations (eg, myelopathy, optic neuropathy, or intellectual changes).

D. Paraproteinemias

A symmetric sensorimotor polyneuropathy that is gradual in onset, progressive in course, and often accompanied by pain and dysesthesia in the limbs may occur in patients (especially men) with multiple myeloma. The neuropathy is of the axonal type in classic lytic myeloma, but segmental demyelination (primary or secondary) and axonal loss may occur in sclerotic myeloma and lead to predominantly motor clinical manifestations. Both demyelinating and axonal neuropathies are also observed in patients with paraproteinemias without myeloma. A small fraction will develop myeloma if serially followed. The demyelinating neuropathy in these patients may be due to the monoclonal protein's reacting to a component of the nerve myelin. The neuropathy of classic multiple myeloma is poorly responsive to therapy. The polyneuropathy of benign monoclonal gammopathy may respond to immunosuppressant drugs and plasmapheresis.

Polyneuropathy may also occur in association with macroglobulinemia and cryoglobulinemia and sometimes responds to plasmapheresis. Entrapment neuropathy, such as carpal tunnel syndrome, is more common than polyneuropathy in patients with (nonhereditary) generalized amyloidosis. With polyneuropathy due to amyloidosis, sensory and autonomic symptoms are especially conspicuous, whereas distal wasting and weakness occur later; there is no specific treatment.

3. Neuropathies Associated with Infectious & Inflammatory Diseases

A. Leprosy

Leprosy is an important cause of peripheral neuropathy in certain parts of the world. Sensory disturbances are mainly due to involvement of intracutaneous nerves. In tuberculoïd leprosy, they develop at the same time and in the same distribution as the skin lesion but may be more extensive if nerve trunks lying beneath the lesion are also involved. In lepromatous leprosy, there is more extensive sensory loss, and this develops earlier and to a greater extent in the coolest regions of the body, such as the dorsal surfaces of the hands and feet, where the bacilli proliferate most actively. Motor deficits result from involvement of superficial nerves where their temperature is lowest, eg, the ulnar nerve in the region proximal to the olecranon groove, the median nerve as it emerges from beneath the forearm flexor muscle to run toward the carpal tunnel, the peroneal nerve at the head of the fibula, and the posterior tibial nerve in the lower part of the leg; patchy facial muscular weakness may also occur owing to involvement of the superficial branches of the seventh cranial nerve.

Motor disturbances in leprosy are suggestive of multiple mononeuropathy, whereas sensory changes resemble those of distal polyneuropathy. Examination, however, relates the distribution of sensory deficits to the temperature of the tissues; in the legs, for example, sparing frequently occurs between the toes and in the popliteal fossa, where the temperature is higher. Treatment is with antileprotic agents (see Chapter 33).

B. AIDS

A variety of neuropathies occur in HIV-infected patients (see Chapter 31). Patients with AIDS may develop a chronic symmetric sensorimotor axonal polyneuropathy associated usually with no abnormal cerebrospinal fluid findings. Treatment is symptomatic. AIDS patients may also develop progressive polyradiculopathy or radiculomyelopathy that leads to leg weakness and urinary retention; sensory loss is less conspicuous than in polyneuropathy. The cerebrospinal fluid may show mononuclear pleocytosis and increased protein and low glucose concentrations. Cytomegalovirus is responsible in at least some cases. The prognosis is generally poor, but some patients respond to intravenous ganciclovir (2.5 mg/kg every 8 hours for 10 days, then 7.5 mg/kg daily 5 days per week).

An inflammatory demyelinating polyradiculoneuropathy sometimes occurs in HIV-seropositive patients without AIDS and may follow an acute, subacute, or chronic course. Weakness is usually more conspicuous distally than proximally and tends to overshadow sensory symptoms. Tendon reflexes are depressed or absent. The cerebrospinal fluid shows an increased cell count and protein concentration. Treatment with plasmapheresis has helped some patients. Spontaneous improvement may also occur. Seropositive patients without AIDS may also develop a mononeuropathy multiplex that sometimes responds to treatment with plasmapheresis.

C. Lyme Borreliosis

The neurologic manifestations of Lyme disease include meningitis, meningoencephalitis, polyradiculoneuropathy, mononeuropathy multiplex, and cranial neuropathy. Serologic tests establish the underlying disorder. Lyme disease and its treatment are discussed in depth in Chapter 34.
D. Sarcoidosis
Cranial nerve palsies (especially facial palsy), multiple mononeuropathy and, less commonly, symmetric polyneuropathy may all occur, the latter sometimes preferentially affecting either motor or sensory fibers. Improvement may occur with use of corticosteroids.

E. Polyarteritis
Involvement of the vasa nervorum by the vasculitic process may result in infarction of the nerve. Clinically, one encounters an asymmetric sensorimotor polyneuropathy (mononeuropathy multiplex) that pursues a waxing and waning course. Corticosteroids and cytotoxic agents—especially cyclophosphamide—may be of benefit in severe cases.

F. Rheumatoid Arthritis
Compressive or entrapment neuropathies, ischemic neuropathies, mild distal sensory polyneuropathy, and severe progressive sensorimotor polyneuropathy can occur in rheumatoid arthritis.

4. Neuropathy Associated with Critical Illness
Patients in intensive care units with sepsis and multiorgan failure sometimes develop polyneuropathies. This may be manifested initially by unexpected difficulty in weaning patients from a mechanical ventilator and in more advanced cases by wasting and weakness of the extremities and loss of tendon reflexes. Sensory abnormalities are relatively inconspicuous. The neuropathy is axonal in type. Its pathogenesis is obscure, and treatment is supportive. The prognosis is good provided patients recover from the underlying critical illness.

5. Toxic Neuropathies
Axonal polyneuropathy may follow exposure to industrial agents or pesticides such as acrylamide, organophosphorus compounds, hexachlorobenzene, methyl bromide, and carbon disulfide; metals such as arsenic, thallium, mercury, and lead; and drugs such as phenytoin, perhexiline, isoniazid, nitrofurantoin, vincristine, and pyridoxine in high doses. Detailed occupational, environmental, and medical histories and recognition of clusters of cases are important in suggesting the diagnosis. Treatment is by preventing further exposure to the causal agent. Isoniazid neuropathy is prevented by pyridoxine supplementation.

Diphtheritic neuropathy results from a neurotoxin released by the causative organism and is common in many areas. Palatal weakness may develop 2–4 weeks after infection of the throat, and infection of the skin may similarly be followed by focal weakness of neighboring muscles. Disturbances of accommodation may occur about 4–5 weeks after infection and distal sensorimotor demyelinating polyneuropathy after 1–3 months.

6. Neuropathies Associated with Malignant Diseases
Both a sensorimotor and a purely sensory polyneuropathy may occur as a nonmetastatic complication of malignant diseases, and have been associated with circulating anti-MAG or anti-Hu antibodies that can be detected by a paraneoplastic antibody panel that is available commercially. The sensorimotor polyneuropathy may be mild and occur in the course of known malignant disease, or it may have an acute or subacute onset, lead to severe disability, and occur before there is any clinical evidence of the cancer, occasionally following a remitting course. An autonomic neuropathy may also occur as a paraneoplastic disorder related to the presence of anti-Hu antibodies or to an antibody against ganglionic acetylcholine receptors (anti-nAChR).

7. Acute Idiopathic Polyneuropathy (Guillain-Barré Syndrome)

ESSENTIALS OF DIAGNOSIS
- Acute or subacute progressive polyradiculoneuropathy.
- Weakness is more severe than sensory disturbances.
- Acute dysautonomia may be life-threatening.

General Considerations
This acute or subacute polyradiculoneuropathy sometimes follows infective illness, inoculations, or surgical procedures. There is an association with preceding Campylobacter jejuni enteritis. The disorder probably has an immunologic basis, but the precise mechanism is unclear.

Clinical Findings
A. Symptoms and Signs
The main complaint is of weakness that varies widely in severity in different patients and often has a proximal emphasis and symmetric distribution. It usually begins in the legs, spreading to a variable extent but frequently involving the arms and often one or both sides of the face. The muscles of respiration or deglutition may also be affected. Sensory symptoms are usually less conspicuous than motor ones, but distal paresthesias and dysesthesias are common, and neuropathic or radicular pain is present in many patients. Autonomic disturbances are also common, may be severe, and are sometimes life-threatening; they include tachycardia, cardiac irregularities, hypertension or hypotension, facial flushing, abnormalities of sweating, pulmonary dysfunction, and impaired sphincter control. The axonal subtypes of the syndrome (acute motor axonal neuropathy [AMAN] and acute motor and sensory axonal neuropathy [AMSAN]) are caused by antibodies to gangliosides on the axon membrane, including
anti-GM1, anti-GM1b, anti-GD1a, anti-GD1b, and (in AMAN) anti-GalNAC-GD1a antibodies. The Miller Fisher syndrome, another subtype, is characterized by the clinical triad of ophthalmoplegia, ataxia, and areflexia, and is associated with anti-GQ1b antibodies.

**B. Laboratory Findings**

The cerebrospinal fluid characteristically contains a high protein concentration with a normal cell content, but these changes may take 2 or 3 weeks to develop. Electrophysiologic studies may reveal marked abnormalities, which do not necessarily parallel the clinical disorder in their temporal course. Pathologic examination shows primary demyelination or, less commonly, axonal degeneration.

**Differential Diagnosis**

When the diagnosis is made, the history and appropriate laboratory studies should exclude the possibility of porphyric, diphtheritic, or toxic (heavy metal, hexacarbon, organophosphate) neuropathies. The temporal course excludes other peripheral neuropathies. Poliomyelitis, botulism, and tick paralysis must also be considered as they cause weakness of acute onset. The presence of pyramidal signs, a markedly asymmetric motor deficit, a sharp sensory level, or early sphincter involvement should suggest a focal cord lesion.

**Treatment**

Treatment with prednisone is ineffective and may prolong recovery time. Plasmapheresis is of value; it is best performed within the first few days of illness and is particularly useful for clinically severe or rapidly progressive cases or those with ventilatory impairment. IVIG (400 mg/kg/d for 5 days) is equally helpful and imposes less stress on the cardiovascular system than plasmapheresis. Patients should be admitted to intensive care units if their forced vital capacity is declining, and intubation is considered if the forced vital capacity reaches 15 mL/kg, the mean inspiratory force reaches –40 mm Hg, dyspnea becomes evident, or the oxygen saturation declines. Respiratory toilet and chest physical therapy help prevent atelectasis. Marked hypotension may respond to volume replacement or pressor agents. Low-dose heparin to prevent pulmonary embolism should be considered.

Approximately 3% of patients with acute idiopathic polyneuropathy have one or more clinically similar relapses, sometimes several years after the initial illness. Plasma exchange therapy may produce improvement in chronic and relapsing inflammatory polyneuropathy.

**Prognosis**

Most patients eventually make a good recovery, but this may take many months, and about 20% of patients are left with persisting disability.

**When to Refer**

All patients should be referred.

---

**When to Admit**

All patients should be hospitalized until their condition is stable and there is no respiratory compromise.

---

**8. Chronic Inflammatory Polyneuropathy**

Chronic inflammatory demyelinating polyneuropathy, an acquired immunologically mediated disorder, is clinically similar to Guillain-Barré syndrome except that it has a relapsing or steadily progressive course over months or years and that autonomic dysfunction is generally less common. It may present as an exclusively motor disorder or with a mixed sensorimotor disturbance. In the relapsing form, partial recovery may occur after some relapses, but in other instances there is no recovery between exacerbations. Although remission may occur spontaneously with time, the disorder frequently follows a progressive downhill course leading to severe functional disability.

Electrodiagnostic studies show marked slowing of motor and sensory conduction, and focal conduction block. Signs of partial denervation may also be present owing to secondary axonal degeneration. Nerve biopsy may show chronic perivascular inflammatory infiltrates in the endoneurium and epineurium, without accompanying evidence of vasculitis. However, a normal nerve biopsy result or the presence of nonspecific abnormalities does not exclude the diagnosis.

Corticosteroids may arrest or reverse the downhill course. Treatment is usually begun with prednisone, 60–80 mg daily, continued for 2–3 months or until a definite response has occurred. If no response has occurred despite 3 months of treatment, a higher dose may be tried. In responsive cases, the dose is gradually tapered, but most patients become corticosteroid-dependent, often requiring prednisone, 20 mg daily on alternate days, on a long-term basis. IVIG can be used in place of, or in addition to corticosteroids and is best used as the initial treatment in pure motor syndromes. When both IVIG and corticosteroids are ineffective, plasma exchange may be worthwhile. Consistent with the notion that the condition is antibody mediated, rituximab has shown promise. Immunosuppressant or immunomodulatory drugs (such as azathioprine) may be added when the response to other...
measures is unsatisfactory or to enable maintenance doses of corticosteroids to be lowered. Symptomatic treatment is also important.

MONONEUROPATHIES

**ESSENTIALS OF DIAGNOSIS**

- Focal motor or sensory deficit.
- Deficit is in territory of an individual peripheral nerve.

An individual nerve may be injured along its course or may be compressed, angulated, or stretched by neighboring anatomic structures, especially at a point where it passes through a narrow space (entrapment neuropathy). The relative contributions of mechanical factors and ischemia to the local damage are not clear. With involvement of a sensory or mixed nerve, pain is commonly felt distal to the lesion. Symptoms develop with or without entrapment neuropathies, resolve rapidly and spontaneously in others, and become progressively more disabling and distressing in yet other cases. The precise neurologic deficit depends on the nerve involved. Percussion of the nerve at the site of the lesion may lead to paresthesias in its distal distribution.

Entrapment neuropathy may be the sole manifestation of subclinical polyneuropathy, and this must be borne in mind and excluded by nerve conduction studies. Such studies are also indispensable for the accurate localization of the focal lesion.

In patients with acute compression neuropathy such as may occur in intoxicated individuals (“Saturday night palsy”), no treatment is necessary. Complete recovery generally occurs, usually within 2 months, presumably because the underlying pathology is demyelination. However, axonal degeneration can occur in severe cases, and recovery then takes longer and may never be complete.

In chronic compressive or entrapment neuropathies, avoidance of aggravating factors and correction of any underlying systemic conditions are important. Local infiltration of the region about the nerve with corticosteroids may be of value; in addition, surgical decompression may help if there is a progressively increasing neurologic deficit or if electrodiagnostic studies show evidence of partial denervation in weak muscles.

Peripheral nerve tumors are uncommon, except in neurofibromatosis type 1, but also give rise to mononeuropathy. This may be distinguishable from entrapment neuropathy only by noting the presence of a mass along the course of the nerve and by demonstrating the precise site of the lesion with appropriate electrophysiologic studies. Treatment of symptomatic lesions is by surgical removal if possible.

**1. Carpal Tunnel Syndrome**

See Chapter 20.

**2. Pronator Teres or Anterior Interosseous Syndrome**

The median nerve gives off its motor branch, the anterior interosseous nerve, below the elbow as it descends into the cubital tunnel. If the condylar groove, the ulnar nerve is exposed to pressure or trauma. Moreover, any increase in the carrying angle of the elbow, whether congenital, degenerative, or traumatic, may cause excessive stretching of the nerve when the elbow is flexed. Ulnar nerve lesions may also result from thickening or distortion of the anatomic structures forming the cubital tunnel, and the resulting symptoms may also be aggravated by flexion of the elbow, because the tunnel is then narrowed by tightening of its roof or inward bulging of its floor. A severe lesion at either site causes sensory changes in the medial 1½ digits and along the medial border of the hand. There is weakness of the ulnar-innervated muscles in the forearm and hand. With a cubital tunnel lesion, however, there may be relative sparing of the flexor carpi ulnaris muscle. Electrophysiologic evaluation using nerve stimulation techniques allows more precise localization of the lesion.

If conservative measures are unsuccessful in relieving symptoms and preventing further progression, surgical treatment may be necessary. This consists of nerve transposition if the lesion is in the condylar groove, or a release procedure if it is in the cubital tunnel.

**3. Ulnar Nerve Lesions**

Ulnar nerve lesions are likely to occur in the elbow region as the nerve runs behind the medial epicondyle and descends into the cubital tunnel. In the condylar groove, the ulnar nerve is exposed to pressure or trauma. Moreover, any increase in the carrying angle of the elbow, whether congenital, degenerative, or traumatic, may cause excessive stretching of the nerve when the elbow is flexed. Ulnar nerve lesions may also result from thickening or distortion of the anatomic structures forming the cubital tunnel, and the resulting symptoms may also be aggravated by flexion of the elbow, because the tunnel is then narrowed by tightening of its roof or inward bulging of its floor. A severe lesion at either site causes sensory changes in the medial 1½ digits and along the medial border of the hand. There is weakness of the ulnar-innervated muscles in the forearm and hand. With a cubital tunnel lesion, however, there may be relative sparing of the flexor carpi ulnaris muscle. Electrophysiologic evaluation using nerve stimulation techniques allows more precise localization of the lesion.

If conservative measures are unsuccessful in relieving symptoms and preventing further progression, surgical treatment may be necessary. This consists of nerve transposition if the lesion is in the condylar groove, or a release procedure if it is in the cubital tunnel.
Ulnar nerve lesions may also develop at the wrist or in the palm of the hand, usually owing to repetitive trauma or to compression from ganglia or benign tumors. They can be subdivided depending on their presumed site. Compressive lesions are treated surgically. If repetitive mechanical trauma is responsible, this is avoided by occupational adjustment or job retraining.

4. Radial Nerve Lesions

The radial nerve is particularly liable to compression or injury in the axilla (eg, by crutches or by pressure when the arm hangs over the back of a chair). This leads to weakness or paralysis of all the muscles supplied by the nerve, including the triceps. Sensory changes may also occur but are often surprisingly inconspicuous, being marked only in a small area on the back of the hand between the thumb and index finger. Injuries to the radial nerve in the spiral groove occur characteristically during deep sleep, as in intoxicated individuals (Saturday night palsy), and there is then sparing of the triceps muscle, which is supplied more proximally. The nerve may also be injured at or above the elbow; its purely motor posterior interosseous branch, supplying the extensors of the wrist and fingers, may be involved immediately below the elbow, but then there is sparing of the extensor carpi radialis longus, so that the wrist can still be extended. The superficial radial nerve may be compressed by handcuffs or a tight watch strap.

5. Femoral Neuropathy

The clinical features of femoral nerve palsy consist of weakness and wasting of the quadriceps muscle, with sensory impairment over the anteromedian aspect of the thigh and sometimes also of the leg to the medial malleolus, and a depressed or absent knee jerk. Isolated femoral neuropathy may occur in diabetics or from compression by retroperitoneal neoplasms or hematomas (eg, expanding aortic aneurysm). Femoral neuropathy may also result from pressure on the inguinal ligament when the thighs are markedly flexed and abducted, as in the lithotomy position.

6. Meralgia Paresthetica

The lateral femoral cutaneous nerve, a sensory nerve arising from the L2 and L3 roots, may be compressed or stretched in obese or diabetic patients and during pregnancy. The nerve usually runs under the outer portion of the inguinal ligament to reach the thigh, but the ligament sometimes splits to enclose it. Hyperextension of the hip or increased lumbar lordosis—such as occurs during pregnancy—leads to nerve compression by the posterior fascicle of the ligament. However, entrapment of the nerve at any point along its course may cause similar symptoms, and several other anatomic variations predispose the nerve to damage when it is stretched. Pain, paresthesia, or numbness occurs about the outer aspect of the thigh, usually unilaterally, and is sometimes relieved by sitting. Examination shows no abnormalities except in severe cases when cutaneous sensation is impaired in the affected area. Symptoms are usually mild and commonly settle spontaneously. Hydrocortisone injections medial to the anterosuperior iliac spine often relieve symptoms temporarily, while nerve decompression by transposition may provide more lasting relief.

7. Sciatic & Common Peroneal (Fibular) Nerve Palsies

Misplaced deep intramuscular injections are probably still the most common cause of sciatic nerve palsy. Trauma to the buttock, hip, or thigh may also be responsible. The resulting clinical deficit depends on whether the whole nerve has been affected or only certain fibers. In general, the peroneal (fibular) fibers of the sciatic nerve are more susceptible to damage than those destined for the tibial nerve. A sciatic nerve lesion may therefore be difficult to distinguish from peroneal (fibular) neuropathy unless there is electromyographic evidence of involvement of the short head of the biceps femoris muscle. The common peroneal (fibular) nerve itself may be compressed or injured in the region of the head and neck of the fibula, eg, by sitting with crossed legs or wearing high boots. There is weakness of dorsiflexion and eversion of the foot, accompanied by numbness or blunted sensation of the anterolateral aspect of the calf and dorsum of the foot.

8. Tarsal Tunnel Syndrome

The tibial nerve, the other branch of the sciatic, supplies several muscles in the lower extremity, gives origin to the sural nerve, and then continues as the posterior tibial nerve to supply the plantar flexors of the foot and toes. It passes through the tarsal tunnel behind and below the medial malleolus, giving off calcaneal branches and the medial and lateral plantar nerves that supply small muscles of the foot and the skin on the plantar aspect of the foot and toes. Compression of the posterior tibial nerve or its branches between the bony floor and ligamentous roof of the tarsal tunnel leads to pain, paresthesias, and numbness over the bottom of the foot, especially at night, with sparing of the heel. Muscle weakness may be hard to recognize clinically. Compressive lesions of the individual plantar nerves may also occur more distally, with clinical features similar to those of the tarsal tunnel syndrome. Treatment is surgical decompression.

9. Facial Neuropathy

An isolated facial palsy is most often idiopathic (Bell palsy) but may occur in patients with HIV seropositivity, sarcoidosis, Lyme disease (Figure 24–2; also see Chapter 34) or with any process causing an inflammatory reaction in the subarachnoid space, such as meningitis. Whenever facial palsies occur bilaterally, or a facial palsy occurs in conjunction with other neurologic deficits, MRI brain imaging should be undertaken and other investigations considered.
sudden onset of lower motor neuron facial palsy.
- Hyperacusis or impaired taste may occur.
- No other neurologic abnormalities.

**General Considerations**

Bell palsy is an idiopathic facial paresis of lower motor neuron type that has been attributed to an inflammatory reaction involving the facial nerve near the stylomastoid foramen or in the bony facial canal. Increasing evidence implicates reactivation of herpes simplex or varicella zoster virus infection in the geniculate ganglion at least in some instances. The disorder is more common in pregnant women or in persons with diabetes mellitus.

**Clinical Findings**

The facial paresis (Figure 24–2) generally comes on abruptly, but it may worsen over the following day or so. Pain about the ear precedes or accompanies the weakness in many cases but usually lasts for only a few days. The face itself feels stiff and pulled to one side. There may be ipsilateral restriction of eye closure and difficulty with eating and fine facial movements. A disturbance of taste is common, owing to involvement of chorda tympani fibers, and hyperacusis due to involvement of fibers to the stapedius occurs occasionally.

**Treatment**

Other disorders that can produce a facial palsy and require specific treatment, such as tumors, Lyme disease, AIDS, sarcoidosis, and herpes zoster infection of the geniculate ganglion, must be excluded. The management of Bell palsy is controversial. Approximately 60% of cases recover completely without treatment, presumably because the lesion is so mild that it leads merely to conduction block. Considerable improvement occurs in most other cases, and only about 10% of all patients have permanent disfigurement or other long-term sequelae. Treatment is unnecessary in most cases but is indicated for patients in whom an unsatisfactory outcome can be predicted. The best clinical guide to progress is the severity of the palsy during the first few days after presentation. Patients with clinically complete palsy when first seen are less likely to make a full recovery than those with an incomplete one. A poor prognosis for recovery is also associated with advanced age, hyperacusis, and severe initial pain. Electromyography and nerve excitability or conduction studies provide a guide to prognosis but not early enough to aid in the selection of patients for treatment.

The only medical treatment that may influence the outcome is administration of corticosteroids, but this must be commenced within 5 days of onset. Treatment with prednisone, 60–80 mg orally daily for 4 or 5 days, followed by tapering of the dose over the next 7–10 days, is a satisfactory regimen; prednisolone (50 mg daily orally) for 10 days is another acceptable alternative. It is helpful to protect the eye with lubricating drops (or lubricating ointment at night) and a patch if eye closure is not possible. Acyclovir does not confer any additional benefit. There is no evidence that surgical procedures to decompress the facial nerve are of benefit.
**DISCOGENIC NECK PAIN**

**ESSENTIALS OF DIAGNOSIS**

- Neck pain, sometimes radiating to arms.
- Restricted neck movements.
- Motor, sensory, or reflex changes in arms with root involvement.
- Neurologic deficit in legs, gait disorder, or sphincter disturbance with cord involvement.

**General Considerations**

A variety of congenital abnormalities may involve the cervical spine and lead to neck pain; these include hemivertebrae, fused vertebrae, basilar impression, and instability of the atlantoaxial joint. Traumatic, degenerative, infective, and neoplastic disorders may also lead to pain in the neck. When rheumatoid arthritis involves the spine, it tends to affect especially the cervical region, leading to pain, stiffness, and reduced mobility; displacement of vertebrae or atlantoaxial subluxation may lead to cord compression that can be life-threatening if not treated by fixation. Further details are given in Chapter 20 (including a discussion on low back pain), and discussion here is restricted to disk disease.

**1. Acute Cervical Disk Protrusion**

Acute cervical disk protrusion leads to pain in the neck and radicular pain in the arm, exacerbated by head movement. With lateral herniation of the disk, motor, sensory, or reflex changes may be found in a radicular (usually C6 or C7) distribution on the affected side (Figure 24–3); with more centrally directed herniations, the spinal cord may also be involved, leading to spastic paraparesis and sensory disturbances in the legs, sometimes accompanied by impaired sphincter function. The diagnosis is confirmed by MRI or CT myelography. In mild cases, bed rest or intermittent neck traction may help, followed by immobilization of the neck in a collar for several weeks. If these measures are unsuccessful or the patient has a significant neurologic deficit, surgical removal of the protruding disk may be necessary.

**2. Cervical Spondylosis**

Cervical spondylosis results from chronic cervical disk degeneration, with herniation of disk material, secondary calcification, and associated osteophytic outgrowths. One or more of the cervical nerve roots may be compressed, stretched, or angulated; and myelopathy may also develop as a result of compression, vascular insufficiency, or recurrent minor trauma to the cord. Patients present with neck pain and restricted head movement, occipital headaches, radicular pain and other sensory disturbances in the arms, weakness of the arms or legs, or some combination of these symptoms. Examination generally reveals that lateral flexion and rotation of the neck are limited. A segmental pattern of weakness or dermatomal sensory loss (or both) may be found unilaterally or bilaterally in the upper limbs, and tendon reflexes mediated by the affected root or roots are depressed. The C5 and C6 nerve roots are most commonly involved, and examination frequently then reveals weakness of muscles supplied by these roots (eg, deltoids, supraspinatus and infraspinatus, biceps, brachioradialis), pain or sensory loss about the shoulder and outer border of the arm and forearm, and depressed biceps and brachioradialis reflexes. Spastic paraparesis may also be present if there is an associated myelopathy, sometimes accompanied by posterior column or spinothalamic sensory deficits in the legs.

Plain radiographs of the cervical spine show osteophyte formation, narrowing of disk spaces, and encroachment on the intervertebral foramina, but such changes are common in middle-aged persons and may be unrelated to the presenting complaint. CT or MRI helps confirm the diagnosis and exclude other structural causes of the myelopathy.

Restriction of neck movements by a cervical collar may relieve pain. Operative treatment may be necessary to prevent further progression if there is a significant neurologic deficit or if root pain is severe, persistent, and unresponsive to conservative measures.

**When to Refer**

- Pain unresponsive to simple measures.
- Patients with neurologic deficits.
- Patients in whom surgical treatment is under consideration.

**When to Admit**

- Patients with progressive or significant neurologic deficit.
- Patients with sphincter involvement (from cord compression).
- Patients requiring surgical treatment.

**BRACHIAL & LUMBAR PLEXUS LESIONS**

**1. Brachial Plexus Neuropathy**

Brachial plexus neuropathy may be idiopathic, sometimes occurring in relationship to a number of different nonspecific illnesses or factors. In other instances, brachial plexus lesions follow trauma or result from congenital anomalies, neoplastic involvement, or injury by various physical agents. In rare instances, the disorder occurs on a familial basis.

Idiopathic brachial plexus neuropathy (neuralgic amyotrophy) characteristically begins with severe pain about the shoulder, followed within a few days by weakness,
reflex changes, and sensory disturbances involving especially the C5 and C6 segments but affecting any nerve in the brachial plexus. Symptoms and signs are usually unilateral but may be bilateral. Wasting of affected muscles is sometimes profound. The disorder relates to disturbed function of cervical roots or part of the brachial plexus, but its precise cause is unknown. Recovery occurs over the ensuing months but may be incomplete. Treatment is purely symptomatic.

2. Cervical Rib Syndrome

Compression of the C8 and T1 roots or the lower trunk of the brachial plexus by a cervical rib or band arising from the seventh cervical vertebra leads to weakness and wasting of intrinsic hand muscles, especially those in the thenar eminence, accompanied by pain and numbness in the medial two fingers and the ulnar border of the hand and forearm. The subclavian artery may also be compressed, and this forms the basis of Adson test for diagnosing the disorder; the radial pulse is diminished or obliterated on the affected side when the seated patient inhales deeply and turns the head to one side or the other. Electromyography, nerve conduction studies, and somatosensory evoked potential studies may help confirm the diagnosis. MRI may be especially helpful in revealing the underlying compressive structure. Plain radiographs or CT scanning sometimes shows the cervical rib or a large
transverse process of the seventh cervical vertebra, but normal findings do not exclude the possibility of a cervical band. Treatment of the disorder is by surgical excision of the rib or band.

3. Lumbosacral Plexus Lesions

A lumbosacral plexus lesion may develop in association with diseases such as diabetes, cancer, or bleeding disorders or in relation to injury. It occasionally occurs as an isolated phenomenon similar to idiopathic brachial plexopathy, and pain and weakness then tend to be more conspicuous than sensory symptoms. The distribution of symptoms and signs depends on the level and pattern of neurologic involvement.

**DISORDERS OF NEUROMUSCULAR TRANSMISSION**

1. Myasthenia Gravis

**ESSENTIALS OF DIAGNOSIS**

- Fluctuating weakness of commonly used voluntary muscles, producing symptoms such as diplopia, ptosis, and difficulty in swallowing.
- Activity increases weakness of affected muscles.
- Short-acting anticholinesterases transiently improve the weakness.

**General Considerations**

Myasthenia gravis occurs at all ages, sometimes in association with a thymic tumor or thyrotoxicosis, as well as in rheumatoid arthritis and lupus erythematosus. It is most common in young women with HLA-DR3; if thymoma is associated, older men are more commonly affected. Onset is usually insidious, but the disorder is sometimes unmasked by a coincidental infection that leads to exacerbation of symptoms. Exacerbations may also occur before the menstrual period and during or shortly after pregnancy. Symptoms are due to a variable degree of block of neuromuscular transmission caused by autoantibodies binding to acetylcholine receptors; these are found in most patients with the disease and have a primary role in reducing the number of functioning acetylcholine receptors. Additionally, cellular immune activity against the receptor is found. Clinically, this leads to weakness; initially powerful movements fatigue readily. The external ocular muscles and certain other cranial muscles, including the masticatory, facial, and pharyngeal muscles, are especially likely to be affected, and the respiratory and limb muscles may also be involved.

**Clinical Findings**

**A. Symptoms and Signs**

Patients present with ptosis, diplopia, difficulty in chewing or swallowing, respiratory difficulties, limb weakness, or some combination of these problems. Weakness may remain localized to a few muscle groups, especially the ocular muscles, or may become generalized. Symptoms often fluctuate in intensity during the day, and this diurnal variation is superimposed on a tendency to longer-term spontaneous relapses and remissions that may last for weeks. Nevertheless, the disorder follows a slowly progressive course and may have a fatal outcome owing to respiratory complications such as aspiration pneumonia.

Clinical examination confirms the weakness and fatigability of affected muscles. In most cases, the extraocular muscles are involved, and this leads to ocular palsies and ptosis, which are commonly asymmetric. Pupillary responses are normal. The bulbar and limb muscles are often weak, but the pattern of involvement is variable. Sustained activity of affected muscles increases the weakness, which improves after a brief rest. Sensation is normal, and there are usually no reflex changes.

Life-threatening exacerbations of myasthenia (so-called myasthenic crisis) may lead to respiratory weakness requiring immediate admission to the intensive care unit, where respiratory function can be monitored and ventilator support is readily available.

**B. Imaging**

A CT scan of the chest with and without contrast should be obtained to demonstrate a coexisting thymoma, but a normal study does not exclude this possibility.

**C. Laboratory and Other Studies**

Electrophysiologic demonstration of a decrementing muscle response to repetitive 2- or 3-Hz stimulation of motor nerves indicates a disturbance of neuromuscular transmission. Such an abnormality may even be detected in clinically strong muscles with certain provocative procedures. Needle electromyography of affected muscles shows a marked variation in configuration and size of individual motor unit potentials, and single-fiber electromyography reveals an increased jitter, or variability, in the time interval between two muscle fiber action potentials from the same motor unit.

Assay of serum for elevated levels of circulating acetylcholine receptor antibodies is useful because it has a sensitivity of 80–90% for the diagnosis of myasthenia gravis. Certain patients without antibodies to acetylcholine receptors have serum antibodies to muscle-specific tyrosine kinase (MuSK), which should therefore be determined; these patients are more likely to have facial, respiratory, and proximal muscle weakness than those with antibodies to acetylcholine receptors.

**Treatment**

Medication such as aminoglycosides that may exacerbate myasthenia gravis should be avoided. Anticholinesterase
patients should be referred.

When to Admit
All patients should be referred.

When to Refer

• Patients with acute exacerbation or respiratory involvement.
• Patients requiring plasmapheresis.
• Patients who are starting corticosteroid therapy.
• For thymectomy.

2. Myasthenic Syndrome (Lambert-Eaton Syndrome)

ESSENTIALS OF DIAGNOSIS

- Variable weakness, typically improving with activity.
- Dysautonomic symptoms may also be present.
- A history of malignant disease may be obtained.

General Considerations
Myasthenic syndrome may be associated with small-cell carcinoma, sometimes developing before the tumor is diagnosed, and occasionally occurs with certain autoimmune diseases. There is defective release of acetylcholine in response to a nerve impulse, caused by P/Q-type voltage-gated calcium-channel antibody, and this leads to weakness, especially of the proximal muscles of the limbs. Unlike myasthenia gravis, however, power steadily increases with sustained contraction. The diagnosis can be confirmed electrophysiologically, because the muscle response to stimulation of its motor nerve increases remarkably if the nerve is stimulated repetitively at high rates, even in muscles that are not clinically weak.

Treatment with plasmapheresis and immunosuppressive drug therapy (prednisone and azathioprine) may lead to clinical and electrophysiologic improvement, in addition to therapy aimed at tumor when present. Prednisone is usually initiated in a daily dose of 60–80 mg and azathioprine in a daily dose of 2 mg/kg. Symptomatic therapy includes the use of potassium channel antagonists; of these, 3,4-diaminopyridine (60–80 mg/d orally in three divided doses) has been best studied and appears efficacious. Guanidine hydrochloride (25–50 mg/kg/d orally in divided doses) is an alternative and is occasionally helpful in seriously disabled patients, but adverse effects of the drug include marrow suppression. The response to treatment with anticholinesterase drugs such as pyridostigmine or neostigmine is usually disappointing.

3. Botulism

The toxin of Clostridium botulinum prevents the release of acetylcholine at neuromuscular junctions and autonomic synapses. Botulism occurs most commonly following the ingestion of contaminated home-canned food and should be suggested by the development of sudden, fluctuating, severe weakness in a previously healthy person. Symptoms begin within 72 hours following ingestion of the toxin and may progress for several days. Typically, there is diplopia, ptosis, facial weakness, dysphagia, and nasal...
speech, followed by respiratory difficulty and finally by weakness that appears last in the limbs. Blurring of vision (with unreactive dilated pupils) is characteristic, and there may be dryness of the mouth, constipation (paralytic ileus), and postural hypotension. Sensation is preserved, and the tendon reflexes are not affected unless the involved muscles are very weak. If the diagnosis is suspected, the local health authority should be notified and a sample of serum and contaminated food (if available) sent to be assayed for toxin. Support for the diagnosis may be obtained by electrophysiologic studies; with repetitive stimulation of motor nerves at fast rates, the muscle response increases in size progressively.

Patients should be hospitalized in case respiratory assistance becomes necessary. Treatment is with trivalent antitoxin, once it is established that the patient is not allergic to horse serum. Potassium channel antagonists may provide symptomatic relief as they do in Lambert-Eaton myasthenic syndrome (see above). Anticholinesterase drugs are of no value. Respiratory assistance and other supportive measures should be provided as necessary. Further details are provided in Chapter 33.

4. Disorders Associated with Use of Aminoglycosides

Aminoglycoside antibiotics, eg, gentamicin, may produce a clinical disturbance similar to botulism by preventing the release of acetylcholine from nerve endings, but symptoms subside rapidly as the responsible drug is eliminated from the body. These antibiotics are particularly dangerous in patients with preexisting disturbances of neuromuscular transmission and are therefore best avoided in patients with myasthenia gravis.

MYOPATHIC DISORDERS

1. Muscular Dystrophies

**ESSENTIALS OF DIAGNOSIS**

- Muscle weakness, often in a characteristic distribution.
- Age at onset and inheritance pattern depend on the specific dystrophy.

**General Considerations**

These inherited myopathic disorders are characterized by progressive muscle weakness and wasting. They are subdivided by mode of inheritance, age at onset, and clinical features, as shown in Table 24–9. In the Duchenne type, pseudohypertrophy of muscles frequently occurs at some stage; intellectual retardation is common; and there may be skeletal deformities, muscle contractures, and cardiac involvement. The serum creatine kinase level is increased, especially in the Duchenne and Becker varieties, and mildly increased also in limb-girdle dystrophy. Electromyography may help confirm that weakness is myopathic rather than neurogenic. Similarly, histopathologic examination of a muscle biopsy specimen may help confirm that weakness is due to a primary disorder of muscle and to distinguish between various muscle diseases.

A genetic defect on the short arm of the X chromosome has been identified in Duchenne dystrophy. The affected gene codes for the protein dystrophin, which is markedly reduced or absent from the muscle of patients with the disease. Dystrophin levels are generally normal in the Becker variety, but the protein is qualitatively altered.

Duchenne muscular dystrophy can now be recognized early in pregnancy in about 95% of women by genetic studies; in late pregnancy, DNA probes can be used on fetal tissue obtained for this purpose by amniocentesis. The genes causing some of the other muscular dystrophies are listed in Table 24–9.

There is no specific treatment for the muscular dystrophies, but it is important to encourage patients to lead as normal lives as possible. Prednisone (0.75 mg/kg orally daily) improves muscle strength and function in boys with Duchenne dystrophy, but side effects need to be monitored. Prolonged bed rest must be avoided, as inactivity often leads to worsening of the underlying muscle disease. Physical therapy and orthopedic procedures may help counteract deformities or contractures.

2. Myotonic Dystrophy

Myotonic dystrophy, a slowly progressive, dominantly inherited disorder, usually manifests itself in the third or fourth decade but occasionally appears early in childhood. Myotonic dystrophy type 1 results from an expanded CTG repeat in a protein kinase gene on chromosome 19; in type 2, the defect is a CCTG repeat expansion in the gene for zinc-finger protein-9 on chromosome 3. Myotonia leads to complaints of muscle stiffness and is evidenced by the marked delay that occurs before affected muscles can relax after a contraction. This can often be demonstrated clinically by delayed relaxation of the hand after sustained grip or by percussion of the belly of a muscle. In addition, there is weakness and wasting of the facial, sternocleidomastoid, and distal limb muscles. Associated clinical features include cataracts, frontal baldness, testicular atrophy, diabetes mellitus, cardiac abnormalities, and intellectual changes. Electromyographic sampling of affected muscles reveals myotonic discharges in addition to changes suggestive of myopathy.

It is difficult to determine whether drug therapy for myotonia is safe or effective. When myotonia is disabling, treatment with a sodium channel blocker—such as phenytoin...

\(^1\)Not all possible genetic loci are shown.

(100 mg orally three times daily), procainamide (0.5–1 g orally four times daily), or mexiletine (150–200 mg orally three times daily)—may be helpful, but the associated side effects, particularly for antiarrhythmic drugs, are often limiting. Neither the weakness nor the course of the disorder is influenced by treatment.

### 3. Myotonia Congenita

Myotonia congenita is commonly inherited as a dominant trait. The responsible gene on chromosome 7 encodes a voltage-gated chloride channel. Generalized myotonia...
without weakness is usually present from birth, but symptoms may not appear until early childhood. Patients complain of muscle stiffness that is enhanced by cold and inactivity and relieved by exercise. Muscle hypertrophy, at times pronounced, is also a feature. A recessive form with later onset is associated with slight weakness and atrophy of distal muscles. Treatment with procainamide, tocainide, mexiletine, or phenytoin may help the myotonia, as in myotonic dystrophy.

4. Polymyositis & Dermatomyositis

See Chapter 20.

5. Inclusion Body Myositis

This disorder, of unknown cause, begins insidiously, usually after middle age, with progressive proximal weakness of first the lower and then the upper extremities, and affecting facial and pharyngeal muscles. Weakness often begins in the quadriceps femoris in the lower limbs and the forearm flexors in the upper limbs. Distal weakness is usually mild. Serum creatine kinase levels may be normal or increased. The diagnosis is confirmed by muscle biopsy. Corticosteroid and immunosuppressive therapy is usually ineffective, but IVIG therapy is occasionally of mild benefit.

6. Mitochondrial Myopathies

The mitochondrial myopathies are a clinically diverse group of disorders that on pathologic examination of skeletal muscle with the modified Gomori stain show characteristic “ragged red fibers” containing accumulations of abnormal mitochondria. Patients may present with progressive external ophthalmoplegia or with limb weakness that is exacerbated or induced by activity. Other patients present with central neurologic dysfunction, eg, myoclonic epilepsy (myoclonic epilepsy, ragged red fiber syndrome, or MERRF), or the combination of myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS). These disorders result from separate abnormalities of mitochondrial DNA. (See also Chapter 20.) Treatment is symptomatic and palliative, but various experimental approaches are being explored.

A mitochondrial myopathy may develop in patients receiving zidovudine for treatment of AIDS, and patients receiving highly active antiretroviral therapy (HAART) for HIV-1 infection may develop a lipodystrophy, with fat accumulating in muscle.

7. Myopathies Associated with Other Disorders

Myopathy may occur in association with chronic hypokalemia, any endocrinopathy, and in patients taking corticosteroids, chloroquine, colchicine, clofibrate, emetine, aminocaproic acid, lovastatin, bretylium tosylate, or drugs causing potassium depletion. Weakness is mainly proximal, and serum creatine kinase is typically normal, except in hypothyroidism and some of the toxic myopathies. Treatment is of the underlying cause. Myopathy also occurs with chronic alcoholism, whereas acute reversible muscle necrosis may occur shortly after acute alcohol intoxication. Inflammatory myopathy may occur in patients taking penicillamine; myotonia may be induced by clofibrate, and preexisting myotonia may be exacerbated or unmasked by depolarizing muscle relaxants (eg, suxamethonium), β-blockers (eg, propranolol), fenoterol, ritodrine and, possibly, certain diuretics.

When to Refer

All patients should be referred (to establish the diagnosis and underlying cause).

When to Admit

- For respiratory assistance.
- For rhabdomyolysis.

Periodic paralysis may have a familial (dominant inheritance) basis. The syndromes to be described are channelopathies that manifest as abnormal, often potassium-sensitive, muscle-membrane excitability and lead clinically to episodes of flaccid weakness or paralysis, sometimes in association with abnormalities of the plasma potassium level. Strength is normal between attacks. Mutations in genes encoding three ion channels [CACNA1S (1q32), SCN4A (17q23.1-q25.3), and KCNJ2 (17q23.1-q24.2)] account for most cases. Hypokalemic periodic paralysis has been related to mutations in the CACNL1A3, SCN4A, or KCNE3 (11q13-q14) gene and is characterized by attacks that tend to occur on awakening, after exercise, or after a heavy meal and may last for several days. Patients should avoid excessive exertion. A low-carbohydrate and low-salt diet may help prevent attacks, as may acetazolamide, 250–750 mg/d. Nonselective β-adrenergic blockers may also prevent recurrent paralytic attacks. An ongoing attack may be aborted by potassium chloride given orally or by intravenous drip, provided the ECG can be monitored and kidney function is satisfactory. In young Asian men, it is commonly associated with hyperthyroidism and has been related to polymorphism in the CACNA1S gene; treatment of the endocrine disorder prevents recurrences. In hyperkalemic periodic paralysis, which is mostly associated with
mutations in the $SCN4A$ gene, attacks also tend to occur after exercise but usually last for $< 1$ hour. They may be terminated by intravenous calcium gluconate (1–2 g) or by intravenous diuretics (furosemide, 20–40 mg), glucose, or glucose and insulin; daily acetazolamide or chlorothiazide may prevent recurrences. **Normokalemic periodic paralysis** is similar clinically to the hyperkalemic variety, but the plasma potassium level remains normal during attacks; treatment is with acetazolamide.

**When to Refer**

All patients should be referred.

Stress & Adjustment Disorders
(Situational Disorders)

Anxiety or depression clearly secondary to an identifiable stress.
Subsequent symptoms of anxiety or depression commonly elicited by similar stress of lesser magnitude.
Alcohol and other drugs are commonly used in self-treatment.

General Considerations

Stress exists when the adaptive capacity of the individual is overwhelmed by events. The event may be an insignificant one objectively considered, and even favorable changes (eg, promotion and transfer) requiring adaptive behavior can produce stress. For each individual, stress is subjectively defined, and the response to stress is a function of each person's personality and physiologic endowment.

Opinion differs about what events are most apt to produce stress reactions. The causes of stress are different at different ages—eg, in young adulthood, the sources of stress are found in the marriage or parent-child relationship, the employment relationship, and the struggle to achieve financial stability; in the middle years, the focus shifts to changing spousal relationships, problems with aging parents, and problems associated with having young adult offspring who themselves are encountering stressful situations; in old age, the principal concerns are apt to be retirement, loss of physical capacity, major personal losses, and thoughts of death.

Clinical Findings

An individual may react to stress by becoming anxious or depressed, by developing a physical symptom, by running away, having a drink, overeating, starting an affair, or in limitless other ways. Common subjective responses are fear (of repetition of the stress-inducing event), rage (at frustration), guilt (over aggressive impulses), and shame (over helplessness). Acute and reactivated stress may be manifested by restlessness, irritability, fatigue, increased startle reaction, and a feeling of tension. Inability to concentrate, sleep disturbances (insomnia, bad dreams), and somatic preoccupations often lead to self-medication, most commonly with alcohol or other central nervous system depressants. Maladaptive behavior in response to stress is called adjustment disorder, with the major symptom specified (eg, "adjustment disorder with depressed mood").

Differential Diagnosis

Adjustment disorders must be distinguished from anxiety disorders, affective disorders, and personality disorders exacerbated by stress and from somatic disorders with psychic overlay. Adjustment disorders may have symptoms that overlap with other disorders, such as anxiety symptoms, but they occur in reaction to an identifiable life stressor such as a difficult work situation or romantic breakup. Adjustment disorders are diagnosed when the symptoms do not fit with a more specific diagnosis such as major depressive disorder which requires at least five criteria. Patients with adjustment disorders have marked distress after a stressor and significant impairment in social or occupational functioning. Adjustment disorders are regarded as acute if less than 6 months or chronic if longer.

Treatment

A. Behavioral

Stress reduction techniques include immediate symptom reduction (eg, rebreathing in a bag for hyperventilation) or early recognition and removal from a stress source before full-blown symptoms appear. It is often helpful for the patient to keep a daily log of stress precipitators, responses, and alleviators. Relaxation, mindfulness-based stress reduction, and exercise techniques are also helpful in reducing the reaction to stressful events.
B. Social

The stress reactions of life crisis problems are a function of psychosocial upheaval, and patients frequently present with somatic symptoms. While it is not easy for the patient to make necessary changes (or they would have been made long ago), it is important for the clinician to establish the framework of the problem, since the patient’s denial system may obscure the issues. Clarifying the problem allows the patient to begin viewing it within the proper context and facilitates the sometimes difficult decisions the patient eventually must make (eg, change of job or relocation of adult-dependent offspring).

C. Psychological

Prolonged in-depth psychotherapy is seldom necessary in cases of isolated stress response or adjustment disorder. Supportive psychotherapy (see above) with an emphasis on the here and now and strengthening of existing coping mechanisms is a helpful approach so that time and the patient’s own resiliency can restore the previous level of function.

D. Medical

Judicious use of sedatives (eg, lorazepam, 0.5–1 mg two or three times daily orally) for a limited time and as part of an overall treatment plan can provide relief from acute anxiety symptoms. Problems arise when the situation becomes chronic through inappropriate treatment or when the treatment approach supports the development of chronicity.

Prognosis

Return to satisfactory function after a short period is part of the clinical picture of this syndrome. Resolution may be delayed if others’ responses to the patient’s difficulties are thoughtlessly harmful or if the secondary gains outweigh the advantages of recovery. The longer the symptoms persist, the worse the prognosis.

POSTTRAUMATIC STRESS DISORDER

ESSENTIALS OF DIAGNOSIS

- Exposure to traumatic (life-threatening) event.
- Symptoms, such as flashbacks, intrusive images, and nightmares, often represent reexperiencing the event.
- Avoidance symptoms, including numbing, social withdrawal, and avoidance of stimuli associated with the event.
- Increased vigilance, such as startle reactions and difficulty falling asleep.
- Symptoms impair functioning.

General Considerations

Posttraumatic stress disorder (PTSD)—included among the anxiety disorders in the Diagnostic Statistical Manual-IV (DSM-IV)—is a syndrome characterized by “reexperiencing” a traumatic event (eg, rape, severe burns, military combat) and decreased responsiveness and avoidance of current events associated with the trauma. The National Veterans Vietnam Readjustment Survey indicated that 53.4% of male and 48.1% of female Vietnam war veterans experienced some symptoms of PTSD, with approximately 60% of these affected veterans experiencing the full syndrome. Of the male veterans, 44.7% experienced a lifetime prevalence of alcohol or drug abuse, with 13% experiencing current abuse or dependence. Data indicate that 13% of veterans who served in Iraq and 6% of those who served in Afghanistan have experienced PTSD. The 2005 National Comorbidity Survey Report estimated the lifetime prevalence of PTSD among adult Americans at 6.8% with a current prevalence of 3.6% and with women having rates twice as high as men. PTSD is more common when the event is associated with physical injury than when it is not. Many individuals with PTSD (20–40%) have experienced other associated problems, including divorce, parenting problems, difficulties with the law, and substance abuse. Since the terrorist attacks in the United States on September 11, 2001, estimates of PTSD have ranged from 4.7% to 10.2% in those witnessing the live attacks and have been associated with functional impairment as well as increased rates of substance use.

Clinical Findings

Patients with PTSD experience physiologic hyperarousal, including startle reactions, intrusive thoughts, illusions, overgeneralized associations, sleep problems, nightmares, dreams about the precipitating event, impulsivity, difficulties in concentration, and hyperalertness. The symptoms may be precipitated or exacerbated by events that are a reminder of the original stress. Symptoms frequently arise after a long latency period (eg, child abuse can result in later-onset posttraumatic stress disorder).

Differential Diagnosis

In 75% of cases, PTSD occurs with comorbid depression or panic disorder, and there is considerable overlap in the symptom complexes of all three conditions. The key to establishing the PTSD diagnosis lies in the history of exposure to a life-threatening event followed by intrusive (eg, flashbacks, nightmares) or avoidance (eg, withdrawal) symptoms. Acute stress disorder occurs during or shortly after a traumatic event and has many of the same symptoms as PTSD but lasts between 2 and 28 days. Some individuals with dissociative features, such as borderline personality disorders, may mimic some of the symptoms of PTSD, but those disorders are typically more related to chronic childhood maltreatment not a specific traumatic event.
Treatment

A. Psychotherapy

Psychotherapy should be initiated as soon as possible after the traumatic event, and it should be brief (typically 8-12 sessions), once the individual is in a safe environment. Cognitive behavior therapy, exposure therapy, and eye-movement desensitization reprocessing have been effective in significantly reducing the duration of symptoms. In all of these approaches, the individual confronts the traumatic situation and learns to view it with less reactivity. Psychological debriefing in a single session, once a mainstay in prevention of PTSD, is now considered to be ineffective and possibly harmful. Posttraumatic stress syndromes respond to interventions that help patients integrate the event in an adaptive way with some sense of mastery in having survived the trauma. Marital problems are a major area of concern, and it is important that the clinician have available a dependable referral source when marriage counseling is indicated.

Treatment initiated later, when symptoms have crystallized, includes programs for cessation of alcohol and other drug abuse, group and individual psychotherapy, and improved social support systems. The therapeutic approach is to facilitate the normal recovery that was blocked at the time of the trauma.

B. Medication

Early treatment of anxious arousal with \( \beta \)-blockers (eg, propranolol, 80–160 mg orally daily) may lessen the peripheral symptoms of anxiety (eg, tremors, palpitations) but has not been shown to help prevent development of PTSD. Antidepressant medications—particularly selective serotonin reuptake inhibitors (SSRIs)—in full dosage are helpful in ameliorating depression, panic attacks, sleep disruption, and startle responses in chronic PTSD. Sertraline and paroxetine are approved by the US Food and Drug Administration (FDA) for this purpose. Antiseizure medications such as carbamazepine (400–800 mg orally daily) will often mitigate impulsivity and difficulty with anger management. Benzodiazepines, such as clonazepam (1–4 mg daily orally, divided into one or two doses), will reduce anxiety and panic attacks when used in adequate dosage, but dependency problems are a concern, particularly when the patient has had such problems in the past. The \( \alpha \)-adrenergic blocking agent prazosin (2–10 mg orally at bedtime) has been successfully used to decrease nightmares and improve quality of sleep in PTSD.

Prognosis

The sooner therapy is initiated after the trauma, the better the prognosis. Approximately half of patients experience chronic symptoms. Prognosis is best in those with good premorbid psychiatric functioning. Individuals experiencing an acute stress disorder typically do better than those experiencing a delayed posttraumatic disorder. Individuals who experience trauma resulting from a natural disaster (eg, earthquake or hurricane) tend to do better than those who experience a traumatic interpersonal encounter (eg, rape or combat).
Clinical Findings

A. Generalized Anxiety Disorder

This is the most common of the clinically significant anxiety disorders. Initial manifestations appear at age 20–35 years, and there is a slight predominance in women. The anxiety symptoms of apprehension, worry, irritability, difficulty in concentrating, insomnia, and somatic complaints are present more days than not for at least 6 months. Manifestations can include cardiac (eg, tachycardia, increased blood pressure), gastrointestinal (eg, increased acidity, nausea, epigastric pain), and neurologic (eg, headache, near-syncopel) systems. The focus of the anxiety may be a number of everyday activities.

B. Panic Disorder

This is characterized by short-lived, recurrent, unpredictable episodes of intense anxiety accompanied by marked physiologic manifestations. Agoraphobia, fear of being in places where escape is difficult, such as open spaces or public places where one cannot easily hide, may be present and may lead the individual to confine his or her life to the home environment. Distressing symptoms and signs such as dyspnea, tachycardia, palpitations, headaches, dizziness, paresthesias, choking, smothering feelings, nausea, and bloating are associated with feelings of impending doom (alarm response). Although these symptoms may lead to overlap with some of the same bodily complaints found in the somatoform disorders, the key to the diagnosis of panic disorder is the psychic pain and suffering the individual expresses. Recurrent sleep panic attacks (not nightmares) occur in about 30% of panic disorders. Anticipatory anxiety develops in all these patients and further constricts their daily lives. Panic disorder tends to be familial, with onset usually under age 25; it affects 3–5% of the population, and the female-to-male ratio is 2:1. The premenstrual period is one of heightened vulnerability. Patients frequently undergo emergency medical evaluations (eg, for “heart attacks” or hypoglycemia) before the correct diagnosis is made. Gastrointestinal symptoms are especially common, occurring in about one-third of cases. Myocardial infarction, pheochromocytoma, hyperthyroidism, and various recreational drug reactions can mimic panic disorder. Mitral valve prolapse may be present but is not usually a significant factor. Patients who have recurrent panic disorder often become demoralized, hypochondriacal, agoraphobic, and depressed. These individuals are at increased risk for major depression and the suicide attempts associated with that disorder. Alcohol abuse (in about 20%) results from self-treatment and is not infrequently combined with dependence on sedatives. Some patients have atypical panic attacks associated with seizure-like symptoms that often include psychomotor phenomena (a history of stimulant abuse often emerges). About 25% of panic disorder patients also have obsessive-compulsive disorder (OCD).

C. Obsessive-Compulsive Disorder

In the obsessive-compulsive reaction, the irrational idea or the impulse persistently intrudes into awareness. Obsessions (constantly recurring thoughts such as fears of exposure to germs) and compulsions (repetitive actions such as washing the hands many times) are recognized by the individual as absurd and are resisted, but anxiety is alleviated only by ritualistic performance of the action or by deliberate contemplation of the intruding idea or emotion. Many patients do not mention the symptoms and must be asked about them. These patients are usually predictable, orderly, conscientious, and intelligent—traits that are seen in many compulsive behaviors such as food binging and purging and compulsive exercise. There is an overlapping of OCD and other behaviors (“OCD spectrum”), including tics, trichotillomania (hair pulling), onychophagia (nail biting), hypochondriasis, Tourette syndrome, and eating disorders (see Chapter 29). The 2–3% incidence of OCD in the general population is much higher than was previously recognized. In addition, there is a high comorbidity of OCD and major depression; two-thirds of OCD patients will develop major depression during their lifetime. Male to female ratios are similar, with the highest rates occurring in the young, divorced, separated, and unemployed (all high-stress categories). Neurologic abnormalities of fine motor coordination and involuntary movements are common. Under extreme stress, these patients sometimes exhibit paranoid and delusional behaviors, often associated with depression, and can mimic schizophrenia.

D. Phobic Disorder

Phobic ideation can be considered a form of “displacement” in which patients transfer feelings of anxiety from their true object to one that can be avoided. However, since phobias are ineffective coping mechanisms, there tends to be an increase in their scope, intensity, and number. Social phobias are global or specific; in the former, all social situations are poorly tolerated, while the latter group includes performance anxiety or well-delineated phobias (eg, fear of bridges). Agoraphobia is frequently associated with severe panic attacks, and it often develops in early adult life, making a normal lifestyle difficult.

E. Dissociative Disorder

Fugue (the sudden, unexpected travel away from one’s home with inability to recall one’s past), amnesia, somnambulism, dissociative identity disorder (multiple personality disorder), and depersonalization are all dissociative states. The reaction is precipitated by emotional crisis. The symptom produces anxiety reduction and a temporary solution of the crisis. Mechanisms include repression and isolation as well as particularly limited scope of attention as seen in hypnotic states. Dissociative symptoms are similar in many ways to symptoms seen in patients with temporal lobe dysfunction.

**Treatment**

In all cases, underlying medical disorders must be ruled out (eg, cardiovascular, endocrine, respiratory, and neurologic disorders and substance-related syndromes, both intoxication and withdrawal states). These and other disorders can coexist with panic disorder.
A. Medical

1. Generalized anxiety—Benzodiazepines are the anxiolytics of choice in the acute management of generalized anxiety (Table 25–1). They are almost immediately effective. Antidepressants can be efficacious for the long-term treatment of generalized anxiety disorder, panic disorder, social phobia, and OCD.

All of the benzodiazepines may be given orally, and several are available in parenteral formulations. Benzodiazepines such as lorazepam are absorbed rapidly when given intramuscularly. In psychiatric disorders, the benzodiazepines are usually given orally; in controlled medical environments (eg, the ICU), where the rapid onset of respiratory depression can be assessed, they are often given intravenously. Onset of action is a function of the rate of absorption (related to lipophilic property) and varies, with diazepam and clorazepate being the most rapidly absorbed orally. This characteristic, along with high lipid solubility, may explain the popularity of diazepam. In the average case of anxiety, diazepam, 5–10 mg orally twice daily as needed, is a reasonable starting regimen.

The duration of action of the benzodiazepines varies as a function of the active metabolites they produce.

²Intermediate physical half-life (10–20 hours).

³Long physical half-life (> 20 hours).

⁴Intravenously for procedures.

⁵Short physical half-life (1–6 hours).

⁶Short physical half-life (about 1 hour).
Benzodiazepines such as lorazepam do not produce active metabolites and have intermediate half-lives of 10–20 hours, characteristics useful in treating elderly patients. Ultra-short-acting agents such as triazolam have half-lives of 1–3 hours and may lead to rebound withdrawal anxiety. Longer-acting benzodiazepines such as flurazepam and diazepam produce active metabolites, have half-lives of 20–120 hours, and should be avoided in the elderly. Since people vary widely in their response and since the medications are long-lasting, the dosage must be individualized. Once this is established, an adequate dose early in the course of symptom development will obviate the need for “pill popping,” which contributes to dependency problems. Panic disorder does not usually respond to benzodiazepines other than clonazepam and alprazolam. Those high-potency benzodiazepines and the antidepressants are most commonly used for panic disorder. Notably, alprazolam has a relatively short half-life and over time can lead to interdose rebound anxiety, although the extended release form is available and obviates this difficulty.

Whether the indications for benzodiazepines are anxiety or insomnia, the medications should be used judiciously. The longer-acting benzodiazepines are used for the treatment of alcohol withdrawal and anxiety symptoms; the intermediate medications are useful as sedatives for insomnia (eg, lorazepam), while short-acting agents (eg, midazolam) are used for medical procedures such as endoscopy.

The side effects of all the benzodiazepine antianxiety agents are patient and dose dependent. As the dosage exceeds the levels necessary for sedation, the side effects include disinhibition, ataxia, dysarthria, nystagmus, and delirium. (The patient should be told not to operate machinery until he or she is well stabilized without side effects.)

Paradoxical agitation, anxiety, psychosis, confusion, mood lability, and anterograde amnesia have been reported, particularly with the shorter-acting benzodiazepines. These agents produce cumulative clinical effects with repeated dosage (especially if the patient has not had time to metabolize the previous dose), additive effects when given with other classes of sedatives or alcohol (many apparently “accidental” deaths are the result of concomitant use of sedatives and alcohol), and residual effects after termination of treatment (particularly in the case of medications that undergo slow biotransformation).

Overdosage results in respiratory depression, hypotension, shock syndrome, coma, and death. Flumazenil, a benzodiazepine antagonist, is effective in overdosage. Overdosage (see Chapter 38) and withdrawal states are medical emergencies. Serious side effects of chronic excessive dosage are development of tolerance, resulting in increasing dose requirements, and physiologic dependence, resulting in withdrawal symptoms similar in appearance to alcohol and barbiturate withdrawal (withdrawal effects must be distinguished from reemergent anxiety). Abrupt withdrawal of sedative medications may cause serious and even fatal convulsive seizures. Psychosis, delirium, and autonomic dysfunction have also been described. Both duration of action and duration of exposure are major factors related to likelihood of withdrawal.

Common withdrawal symptoms after low to moderate daily use of benzodiazepines are classified as somatic (disturbed sleep, tremor, nausea, muscle aches), psychological (anxiety, poor concentration, irritability, mild depression), or perceptual (poor coordination, mild paranoia, mild confusion). The presentation of symptoms will vary depending on the half-life of the drug. There are no significant side effects on organ systems other than the brain, and the medications are safe in most medical conditions. Benzodiazepine interactions with other medications are listed in Table 25–2.

Antidepressants are the first-line medications for sustained treatment of generalized anxiety disorder, having the advantage of not causing serious physiologic dependency problems. At initiation of treatment, antidepressants can themselves be anxiogenic—thus, an initial dose, in conjunction with short-term treatment with a benzodiazepine, is often indicated. Venlafaxine and duloxetine (serotonin and norepinephrine reuptake inhibitors) are FDA-approved for the treatment of generalized anxiety disorder in usual antidepressant doses. Initial daily dosing should start low (37.5–75 mg for venlafaxine and 30 mg for duloxetine) and be titrated upward as needed. SSRIs, such as paroxetine, are also used. Similarly, buspirone, sometimes used as an augmenting agent in the treatment of depression and compulsive behaviors, is also effective for generalized anxiety. Buspirone is usually given in a total dosage of 15–60 mg/d in three divided doses. Higher doses tend to be counterproductive and produce gastrointestinal symptoms and dizziness. There is a 2- to 4-week delay before antidepressants and buspirone take effect, and patients require education regarding this lag. Sleep is sometimes negatively affected. β-Blockers such as propranolol may help reduce peripheral somatic symptoms. Alcohol is the most frequently self-administered drug and should be interdicted. The highly addicting medications with a narrow margin of safety such as glutethimide, ethchlorvynol, methyprylon, meperbamate, and the barbiturates (with the exception of phenobarbital) should be

avoided. Phenobarbital, in addition to its anticonvulsant properties, is a reasonably safe and very inexpensive sedative but has the disadvantage of causing hepatic microsomal enzyme stimulation (not the case with benzodiazepines), which may affect the metabolism of other medications.

2. Panic attacks—Panic attacks may be treated in several ways. A sublingual dose of alprazolam (0.5–1 mg) is often effective for urgent treatment. For sustained treatment, SSRIs are the initial medications of choice (adequate blood levels will require dosages similar to those used in the treatment of depression). For example, sertraline starting at 25 mg/d and increased after 1 week to 50 mg/d may be effective. Because of initial agitation in response to antidepressants, doses should start low and be very gradually increased. High-potency benzodiazepines may be used for symptomatic treatment as the antidepressant dose is titrated upward. Clonazepam (1–6 mg/d orally) and alprazolam (0.5–6 mg/d orally) are effective alternatives to antidepressants. Both medications may produce marked withdrawal if stopped abruptly and should always be tapered. Because of chronicity of the disorders and the problem of dependency with benzodiazepine medications, it is generally desirable to use antidepressant medications as the principal pharmacologic approach. Antidepressants have been used in conjunction with β-blockers in resistant cases. Propranolol (40–160 mg/d orally) can mute the peripheral symptoms of anxiety without significantly affecting motor and cognitive performance. They block symptoms mediated by sympathetic stimulation (eg, palpitations, tremulousness) but not nonadrenergic symptoms (eg, diarrhea, muscle tension). Contrary to a common misunderstanding, they usually do not cause depression as a side effect and can be used cautiously in patients with depression. Valproate has been found to be as effective in panic disorder as the antidepressants and is another useful alternative.

3. Phobic disorder—Phobic disorder may be part of the panic disorder and is treated within that framework. Global social phobias may be treated with SSRIs, such as paroxetine, sertraline, and fluoxetine, or monoamine oxidase (MAO) inhibitors in the same dosage as used for depression. Gabapentin, an anticonvulsant with anxiolytic properties, is a reasonably safe and very inexpensive sedative but has the disadvantage of causing hepatic microsomal enzyme stimulation (not the case with benzodiazepines), which may affect the metabolism of other medications. Phenobarbital, in addition to its anticonvulsant properties, is a reasonably safe and very inexpensive sedative but has the disadvantage of causing hepatic microsomal enzyme stimulation (not the case with benzodiazepines), which may affect the metabolism of other medications.

C. Psychological

Cognitive behavioral approaches have been effective in treatment of panic disorders, phobias, and OCD when erroneous beliefs need correction. These approaches share a common behavioral technique of exposing the individual to the feared object or situation. The combination of medical and cognitive behavioral therapy is more effective than either alone. Group therapy is the treatment of choice when the anxiety is clearly a function of the patient’s difficulties in dealing with social settings. Acceptance and commitment therapy is a new psychotherapy that has been used with some success in anxiety disorders. It encourages individuals to keep focused on life goals while they “accept” the presence of anxiety in their lives.

D. Social

Peer support groups for panic disorder and agoraphobia have been particularly helpful. Social modification may require measures such as family counseling to aid acceptance of the patient’s symptoms and avoid counterproductive behavior in behavioral training. Any help in maintaining the social structure is anxiety-alleviating, and work, school, and social activities should be maintained. School and vocational counseling may be provided by professionals, who often need help from the clinician in defining the patient’s limitations.
PROGNOSIS

Anxiety disorders are usually long-standing and may be quite difficult to treat. All can be relieved to varying degrees with medications and behavioral techniques. The prognosis is much better if the commonly observed anxiety-panic-phobia-depression cycle can be broken with a combination of the therapeutic interventions discussed above.

SOMATOFORM DISORDERS (Abnormal Illness Behaviors)

ESSENTIALS OF DIAGNOSIS

- Physical symptoms may involve one or more organ systems and are not intentional.
- Subjective complaints exceed objective findings.
- Correlations of symptom development and psychosocial stresses.
- Combination of biogenetic and developmental patterns.

GENERAL CONSIDERATIONS

Somatoform disorders can occur focused on any organ system. Vulnerability in one or more organ systems and exposure to family members with somatization problems play a major role in the development of particular symptoms, and the "functional" versus "organic" dichotomy is a hindrance to good treatment. Clinicians should suspect psychiatric disorders in a number of conditions. For example, 45% of patients complaining of palpitations had lifetime psychiatric diagnoses including generalized anxiety, depression, panic, and somatization disorders. Similarly, 33–44% of patients who undergo coronary angiography for chest pain but have negative results have been found to have panic disorder.

In any patient presenting with a condition judged to be somatoform, depression must be considered in the diagnosis.

CLINICAL FINDINGS

A. Conversion Disorder

“Conversion” (formerly “hysterical conversion”) of psychic conflict into physical symptoms in parts of the body innervated by the sensorimotor system (eg, paralysis, aphony) is a disorder that is more common in individuals from lower socioeconomic classes and certain cultures. The coping mechanisms used in this condition are repression (a barrier from consciousness) and isolation (a splitting of the affect from the idea). The somatic manifestation that takes the place of anxiety is often paralysis, and in some instances the organ dysfunction may have symbolic meaning (eg, arm paralysis in marked anger so the individual cannot use the arm to strike someone). Pseudoepileptic ("hysterical") seizures are often difficult to differentiate from intoxication states or panic attacks. Retention of consciousness, random flailing with asynchronous movements of the right and left sides, and resistance to having the nose and mouth pinched closed during the attack, all point toward a pseudoepileptic event. Electroencephalography, particularly in a video-electroencephalography assessment unit, during the attack is the most helpful diagnostic aid in excluding genuine seizure states. Serum prolactin levels rise abruptly in the postictal state only in true epilepsy. La belle indifférence (an unconcerned affect) is not a significant identifying characteristic, as commonly believed, since individuals even with genuine medical illness, may exhibit a high level of denial. Important conversion disorder criteria include a history of conversion or somatization disorder, modeling the symptom after someone else who had a similar presentation, a serious precipitating emotional event, associated psychopathology (eg, depression, schizophrenia, personality disorders), a temporal correlation between the precipitating event and the symptom, and a temporary “solving of the problem” by the conversion. It is important to identify physical disorders with unusual presentations (eg, multiple sclerosis, systemic lupus erythematosus).

B. Somatization Disorder (Briquet Syndrome, Hysteria)

This is characterized by multiple physical complaints referable to several organ systems. Anxiety, panic disorder, and depression are often present, and major depression is an important consideration in the differential diagnosis. There is a significant relationship (20%) to a lifetime history of panic-agoraphobia-depression. It usually occurs before age 30 and is ten times more common in women. Polysurgery is often a feature of the history. Preoccupation with medical and surgical therapy becomes a lifestyle that excludes most other activities. The symptoms indicate maladaptive coping techniques and there is often evidence of long-standing somatic complaints, including multiple pain and gastrointestinal symptoms (such as dyspareunia, dysmenorrhea, headache, backache, abdominal pain, vomiting, bloating) and pseudoneurologic symptoms (such as amnesia or pseudoepileptic seizures), often with a history of similar organ system involvement in other family members. Multiple symptoms that constantly change and the
are strong clues to the problem.

C. Pain Disorder Associated with Psychological Factors (Formerly Somatoform Pain Disorder)

This involves a long history of complaints of severe pain out of proportion to any biomedical findings that are present. This diagnosis must not be one of exclusion and should be made only after extended evaluation has established a clear correlation of psychogenic factors with exacerbations and remissions of complaints.

D. Hypochondriasis

This is a fear of disease and preoccupation with the body, with perceptual amplification and heightened responsiveness. A process of social learning is usually involved, frequently with a role model who was a member of the family and may be a part of the underlying psychodynamic causation. It is common in panic disorders.

E. Factitious Disorders

These disorders, in which symptom production is intentional, are not somatoform conditions in that symptoms are produced consciously, in contrast to the unconscious process of the above conditions. They are characterized by self-induced symptoms or false physical and laboratory findings for the purpose of deceiving clinicians or other hospital personnel. The deceptions may involve self-mutilation, fever, hemorrhage, hypoglycemia, seizures, and an almost endless variety of manifestations—often presented in an exaggerated and dramatic fashion (Munchausen syndrome). “Munchausen by proxy” is the term used when a parent creates an illness in a child so the adult (usually the mother) can maintain a relationship with clinicians. The duplicity may be either simple or extremely complex and difficult to recognize. The patients are frequently connected in some way with the health professions; they are often migratory; and there is no apparent external motivation other than achieving the patient role.

Complications

A poor clinician-patient relationship, with iatrogenic disorders and “doctor shopping,” tends to exacerbate the problem. Sedative and analgesic dependency is the most common iatrogenic complication.

Treatment

A. Medical

Medical support with careful attention to building a therapeutic practitioner-patient relationship is the mainstay of treatment. It must be accepted that the patient’s distress is real. Every problem not found to have an organic basis is not necessarily a mental disease. Diligent attempts should be made to relate symptoms to adverse developments in the patient’s life. It may be useful to have the patient keep a meticulous diary, paying particular attention to various pertinent factors evident in the history. Regular, frequent, short appointments that are not symptom-contingent may be helpful. Medications (frequently abused) should not be prescribed to replace appointments. One person should be the primary clinician, and consultants should be used mainly for evaluation. An empathic, realistic, optimistic approach must be maintained in the face of the expected ups and downs. Ongoing reevaluation is necessary, since somatization can coexist with a concurrent physical illness.

B. Psychological

Psychological approaches can be used by the primary clinician when it is clear that the patient is ready to make some changes in lifestyle in order to achieve symptomatic relief. This is often best approached on a here-and-now basis and oriented toward pragmatic changes rather than an exploration of early experiences that the patient frequently fails to relate to current distress. Group therapy with other individuals who have similar problems is sometimes of value to improve coping, allow ventilation, and focus on interpersonal adjustment. Hypnosis or lorazepam interviews used early are helpful in resolving conversion disorders. If the primary clinician has been working with the patient on psychological problems related to the physical illness, the groundwork is often laid for successful psychiatric referral.

For patients who have been identified as having a factitious disorder, early psychiatric consultation is indicated. There are two main treatment strategies for these patients. One consists of a conjoint confrontation of the patient by both the primary clinician and the psychiatrist. The patient’s disorder is portrayed as a cry for help, and psychiatric treatment is recommended. The second approach avoids direct confrontation and attempts to provide a face-saving way to relinquish the symptom without overt disclosure of the disorder’s origin. Techniques such as biofeedback and self-hypnosis may foster recovery using this strategy. Another face-saving approach is to use a double bind with the patient. For example, the patient is told there are two possible diagnoses: (1) an organic disease that should respond to the next medical intervention (usually modest and noninvasive), or (2) factitious disorder for which the patient will need psychiatric treatment. Given these options, many patients will choose to recover and not have to admit the origin of their problem.

C. Behavioral

Behavioral therapy is probably best exemplified by biofeedback techniques. In biofeedback, the particular abnormality (eg, increased peristalsis) must be recognized and monitored by the patient and therapist (eg, by an electronic stethoscope to amplify the sounds). This is immediate feedback, and after learning to recognize it, the patient can then learn to identify any change thus produced (eg, a decrease in bowel sounds) and so become a conscious originator of the feedback instead of a passive recipient. Relief of the symptom operantly conditions the patient to utilize the maneuver that relieves symptoms (eg, relaxation causing a decrease in bowel sounds). With emphasis on this
type of learning, the patient is able to identify symptoms early and initiate the countermeasures, thus decreasing the symptomatic problem. Migrainoid and tension headaches have been particularly responsive to biofeedback methods.

D. Social

Social endeavors include family, work, and other interpersonal activity. Family members should come for some appointments with the patient so they can learn how best to live with the patient. This is particularly important in treatment of somatization and pain disorders. Peer support groups provide a climate for encouraging the patient to accept and live with the problem. Ongoing communication with the employer may be necessary to encourage long-term continued interest in the employee. Employers can become just as discouraged as clinicians in dealing with employees who have chronic problems.

Prognosis

The prognosis is much better if the primary clinician is able to intervene early before the situation has deteriorated. After the problem has crystallized into chronicity, it is very difficult to effect change.

CHRONIC PAIN DISORDERS

ESSENTIALS OF DIAGNOSIS

- Chronic complaints of pain.
- Symptoms frequently exceed signs.
- Minimal relief with standard treatment.
- History of having seen many clinicians.
- Frequent use of several nonspecific medications.

General Considerations

A problem in the management of pain is the lack of distinction between acute and chronic pain syndromes. Most clinicians are adept at dealing with acute pain problems but have difficulty handling the patient with a chronic pain disorder. This type of patient frequently takes too many medications, stays in bed a great deal, has seen many clinicians, has lost skills, and experiences little joy in either work or play. All relationships suffer (including those with clinicians), and life becomes a constant search for succor. The search results in complex clinician-patient relationships that usually include many drug trials, particularly sedatives, with adverse consequences (eg, irritability, depressed mood) related to long-term use. Treatment failures provoke angry responses and depression from both the patient and the clinician, and the pain syndrome is exacerbated. When frustration becomes too great, a new clinician is found, and the cycle is repeated. The longer the existence of the pain disorder, the more important become the psychological factors of anxiety and depression. As with all other conditions, it is counterproductive to speculate about whether the pain is “real.” It is real to the patient, and acceptance of the problem must precede a mutual endeavor to alleviate the disturbance.

Clinical Findings

Components of the chronic pain syndrome consist of anatomic changes, chronic anxiety and depression, anger, and changed lifestyle. Usually, the anatomic problem is irreversible, since it has already been subjected to many interventions with increasingly unsatisfactory results. An algorithm for assessing chronic pain and differentiating it from other psychiatric conditions is illustrated in Figure 25–1.

Chronic anxiety and depression produce heightened irritability and overreaction to stimuli. A marked decrease in pain threshold is apparent. This pattern develops into a hypochondriacal preoccupation with the body and a constant need for reassurance. The pressure on the clinician becomes wearing and often leads to covert rejection of the patient, such as not being available or making referrals to other clinicians.

This is perceived by the patient, who then intensifies the effort to find help, and the typical cycle is repeated. Anxiety and depression are seldom discussed, almost as if there is a tacit agreement not to deal with these issues.

Changes in lifestyle involve some of the pain behaviors. These usually take the form of a family script in which the patient accepts the role of being sick, and this role then becomes the focus of most family interactions and may become important in maintaining the family, so that neither the patient nor the family wants the patient’s role to change. Demands for attention and efforts to control the behavior of others revolve around the central issue of control of other people (including clinicians). Cultural factors frequently play a role in the behavior of the patient and how the significant people around the patient cope with the problem. Some cultures encourage demonstrative behavior, while others value the stoic role.

Another secondary gain that frequently maintains the patient in the sick role is financial compensation or other benefits. Frequently, such systems are structured so that they reinforce the maintenance of sickness and discourage any attempts to give up the role. Clinicians unwittingly reinforce this role because of the very nature of the practice of medicine, which is to respond to complaints of illness. Helpful suggestions from the clinician are often met with responses like, “Yes, but ….” Medications then become the principal approach, and drug dependency problems may develop.
A. Behavioral

The cornerstone of a unified approach to chronic pain syndromes is a comprehensive behavioral program. This is necessary to identify and eliminate pain reinforcers, to decrease drug use, and to use effectively those positive reinforcers that shift the focus from the pain. It is critical that the patient be made a partner in the effort to manage and function better in the setting of ongoing pain symptoms. The clinician must shift from the idea of biomedical cure to ongoing care of the patient. The patient should agree to discuss the pain only with the clinician and not with family members; this tends to stabilize the patient's personal life, since the family is usually tired of the subject. At the beginning of treatment, the patient should be assigned self-help tasks graded up to maximal activity as a means of positive reinforcement. The tasks should not exceed capability. The patient can also be asked to keep a self-rating chart to log accomplishments, so that progress can be measured and remembered. Instruct the patient to record degrees of pain on a self-rating scale in relation to various situations and mental attitudes so that similar circumstances can be avoided or modified.

Avoid positive reinforcers for pain such as marked sympathy and attention to pain. Emphasize a positive response to productive activities, which remove the focus of attention from the pain. Activity is also desensitizing, since the patient learns to tolerate increasing activity levels.

Biofeedback techniques (see Somatoform Disorders, above) and hypnosis have been successful in ameliorating some pain syndromes. Hypnosis tends to be most effective in patients with a high level of denial, who are more responsive to suggestion. Hypnosis can be used to lessen anxiety, alter perception of the length of time that pain is experienced, and encourage relaxation. Mindfulness-based stress reduction programs have been useful in helping individuals develop an enhanced capacity to live a higher quality life with persistent pain.

B. Medical

A single clinician in charge of the comprehensive treatment approach is the highest priority. Consultations as indicated
and technical procedures done by others are appropriate, but the care of the patient should remain in the hands of the primary clinician. Referrals should not be allowed to raise the patient’s hopes unrealistically or to become a way for the clinician to reject the case. The attitude of the clinician should be one of honesty, interest, and helpfulness—not for a cure but for control of pain and improved function. If the patient manifests opioid addiction, detoxification may be an early treatment goal.

Nonsteroidal anti-inflammatory medications are often the first-line of treatment for pain. If opioid analgesics or sedatives are prescribed, they should not be given on an “as-needed” schedule (see Chapter 5). A fixed schedule lessens the conditioning effects of these medications. Tricyclic antidepressants (TCAs) (eg, nortriptyline), venlafaxine, and duloxetine in doses up to those used in depression may be helpful, particularly in neuropathic pain syndromes. In other conditions, their effects on pain may be less clear, but ameliorating depression is usually important nonetheless. Gabapentin, an anticonvulsant with possible applications in the treatment of anxiety disorders, has been shown to be useful in postherpetic and diabetic neuropathies and somatoform disorders.

In addition to medications, a variety of nonpharmacologic strategies may be offered, including physical therapy and acupuncture.

C. Social
Involvement of family members and other significant persons in the patient’s life should be an early priority. The best efforts of both patient and therapists can be unwittingly sabotaged by other persons who may feel that they are “helping” the patient. They frequently tend to reinforce the negative aspects of the chronic pain disorder. The patient becomes more dependent and less active, and the pain syndrome becomes an immutable way of life. The more destructive pain behaviors described by many experts in chronic pain disorders are the results of well-meaning but misguided efforts of family members. Ongoing therapy with the family can be helpful in the early identification and elimination of these behavior patterns.

D. Psychological
In addition to group therapy with family members and others, groups of patients can be helpful if properly led. The major goal, whether of individual or group therapy, is to gain patient involvement. A group can be a powerful instrument for achieving this goal, with the development of group loyalties and cooperation. People will frequently make efforts with group encouragement that they would never make alone. Individual therapy should be directed toward strengthening existing coping mechanisms and improving self-esteem. For example, teaching patients to challenge expectations induced by chronic pain may lead to improved functioning. As an illustration, many chronic pain patients, making assumptions more derived from acute injuries, incorrectly believe they will damage themselves by attempting to function. The rapport between patient and clinician, as in all psychotherapeutic efforts, is the major factor in therapeutic success.

PSYCHOSEXUAL DISORDERS

The stages of sexual activity include excitement (arousal), orgasm, and resolution. The precipitating excitement or arousal is psychologically determined. Arousal response leading to plateau is a physiologic and psychological phenomenon of vasocongestion, a parasympathetic reaction causing erection in men and labial-clitoral congestion in women. The orgasmic response includes emission in men and clonic contractions of the analogous striated perineal muscles of both men and women. Resolution is a gradual return to normal physiologic status.

While the arousal stimuli—vasocongestive and orgasmic responses—constitute a single response in a well-adjusted person, they can be considered as separate stages that can produce different syndromes responding to different treatment procedures.

Clinical Findings

There are three major groups of sexual disorders.

A. Paraphilias (Sexual Arousal Disorders)

In these conditions, formerly called “deviations” or “variations,” the excitement stage of sexual activity is associated with sexual objects or orientations different from those usually associated with adult sexual stimulation. The stimulus may be a woman’s shoe, a child, animals, instruments of torture, or incidents of aggression. The pattern of sexual stimulation is usually one that has early psychological roots. Poor experiences with sexual activity frequently reinforce this pattern over time.

Exhibitionism is the impulsive behavior of exposing the genitalia to unsuspecting strangers in order to achieve sexual excitement. It is a childhood sexual behavior carried into adult life.

Transvestism consists of recurrent cross-dressing behavior in a heterosexual man for the purpose of sexual excitation. Such fetishesitic behavior can be part of masturbation play. Transvestism in homosexuality and transsexualism is not for the purpose of sexual excitement but is a function of preference or gender identity disorder.

Voyeurism involves the achievement of sexual arousal by watching the activities of an unsuspecting person, usually in various stages of undress or sexual activity. In both exhibitionism and voyeurism, excitation leads to masturbation as a replacement for sexual activity.

Pedophilia is the use of a child of either sex to achieve sexual arousal and, in many cases, gratification. Contact is frequently oral, with either participant being dominant, but pedophilia includes intercourse of any type. Adults of both sexes engage in this behavior, but because of social and cultural factors it is more commonly identified with men.
The pedophile has difficulty in adult sexual relationships, and men who perform this act are frequently impotent.

Incest involves a sexual relationship with a person in the immediate family, most frequently a child. In many ways it is similar to pedophilia (intrafamilial pedophilia). Incestuous feelings are fairly common, but cultural mores are usually sufficiently strong to act as a barrier to the expression of sexual feelings.

Sexual sadism is the attainment of sexual arousal by inflicting pain upon the sexual object. Much sexual activity has aggressive components (eg, biting, scratching). However, forced sexual acquiescence (eg, rape) is considered to be primarily an act of aggression.

Sexual masochism is the achievement of erotic pleasure by being humiliated, enslaved, physically bound, and restrained. It may be life-threatening, since neck binding or partial asphyxiation usually forms part of the ritual. The practice is much more common in men than in women.

B. Gender Identity Disorder

Core gender identity reflects a biologic self-image—the conviction that “I am a boy” or “I am a girl” that is usually well developed by age 3 or 4. Gender dysphoria refers to the development of a sexual identity that is the opposite of the biologic one.

Transsexualism is an attempt to deny and reverse biologic sex by maintaining sexual identity with the opposite gender. Transsexuals do not alternate between gender roles; rather, they assume a fixed role of attitudes, feelings, fantasies, and choices consonant with those of the opposite sex, all of which clearly date back to early development. For example, male to female transsexuals in early childhood behave, talk, and fantasize as if they were girls. They do not grow out of feminine patterns; they do not work in professions traditionally considered to be masculine; and they have no interest in their own penises either as evidence of maleness or as organs for erotic behavior. The desire for sex change starts early and may culminate in assumption of a feminine lifestyle, hormonal treatment, and use of surgical procedures, eg, castration and vaginoplasty.

C. Psychosexual Dysfunction

This category includes a large group of vasocongestive and orgasmic disorders. Often, they involve problems of sexual adaptation, education, and technique that are often initially discussed with, diagnosed by, and treated by the primary care provider.

There are two conditions common in men: erectile dysfunction and ejaculation disturbances.

Erectile dysfunction is inability to achieve or maintain an erection firm enough for satisfactory intercourse; patients sometimes use the term to mean premature ejaculation. Careful questioning is necessary, since causes of this vasocongestive disorder can be psychological, physiologic, or both. The majority are pathophysiologic and, to varying degrees, treatable. After onset of the problem, a history of occasional erections—especially nocturnal penile tumescence, which may be evaluated by a simple monitoring device, or a sleep study in the sleep laboratory—is usually evidence that the dysfunction is psychological in origin, with the caveat that decreased nocturnal penile tumescence occurs in some depressed patients. Psychological erectile dysfunction is caused by interpersonal or intrapsychic factors (eg, marital disharmony, depression). Organic factors are discussed in Chapter 23.

Ejaculation disturbances include premature ejaculation, inability to ejaculate, and retrograde ejaculation. Ejaculation is usually connected with orgasm, and ejaculatory control is an acquired behavior that is minimal in adolescence and increases with experience. Pathogenic factors are those that interfere with learning control, most frequently sexual ignorance. Intrapsychic factors (anxiety, guilt, depression) and interpersonal maladaptation (marital problems, unresponsiveness of mate, power struggles) are also common. Organic causes include interference with sympathetic nerve distribution (often due to surgery or trauma) and the effects of pharmacologic agents (eg, SSRIs or sympatholytics).

In women, the two most common forms of sexual dysfunction are vaginismus and frigidity.

Vaginismus is a conditioned response in which a spasm of the perineal muscles occurs if there is any stimulation of the area. The desire is to avoid penetration. Sexual responsiveness and vasocongestion may be present, and orgasm can result from clitoral stimulation.

Frigidity is a complex condition in which there is a general lack of sexual responsiveness. The woman has difficulty in experiencing erotic sensation and does not have the vasocongestive response. Sexual activity varies from active avoidance of sex to an occasional orgasm. Orgasmic dysfunction—in which a woman has a vasocongestive response but varying degrees of difficulty in reaching orgasm—is sometimes differentiated from frigidity. Causes for the dysfunctions include poor sexual techniques, early traumatic sexual experiences, interpersonal disharmony (marital struggles, use of sex as a means of control), and intrapsychic problems (anxiety, fear, guilt). Organic causes include any conditions that might cause pain in intercourse, pelvic pathology, mechanical obstruction, and neurologic deficits.

Disorders of sexual desire consist of diminished or absent libido in either sex and may be a function of organic or psychological difficulties (eg, anxiety, phobic avoidance). Any chronic illness can reduce desire. Hormonal disorders, including hypogonadism or use of antiandrogen compounds such as cyproterone acetate, and chronic kidney disease contribute to deterioration in sexual desire. Although menopause may lead to diminution of sexual desire in some women, the relationship between menopause and libido is complicated and may be influenced by sociocultural factors. Alcohol, sedatives, opioids, marijuana, and some medications may affect sexual drive and performance.

Treatment

A. Paraphilias and Gender Identity Disorders

1. Psychological—Sexual arousal disorders involving variant sexual activity (paraphilia), particularly those of a more superficial nature (eg, voyeurism) and those of recent onset, are responsive to psychotherapy in a moderate
percentage of cases. The prognosis is much better if the motivation comes from the individual rather than the legal system; unfortunately, however, judicial intervention is frequently the only stimulus to treatment, because the condition persists and is reinforced until conflict with the law occurs. Therapies frequently focus on barriers to normal arousal response; the expectation is that the variant behavior will decrease as normal behavior increases.

2. Behavioral—Aversive and operant conditioning techniques have been tried frequently in gender role disorders but have only occasionally been successful. In some cases, the sexual arousal disorders improve with modeling, role-playing, and conditioning procedures. Emotive imagery is occasionally helpful in lessening anxiety in fetish problems.

3. Social—Although they do not produce a change in sexual arousal patterns or gender role, self-help groups have facilitated adjustment to an often hostile society. Attention to the family is particularly important in helping persons in such groups to accept their situation and alleviate their guilt about the role they think they had in creating the problem.

4. Medical—Medroxyprogesterone acetate, a suppressor of libidinal drive, is used to mute disruptive sexual behavior in men of all ages. Onset of action is usually within 3 weeks, and the effects are generally reversible. Fluoxetine or other SSRIs at depression doses (see Table 25–8) may reduce some of the compulsive sexual behaviors including the paraphilias. A focus of study in the treatment of severe paraphilia has been agonists of luteinizing hormone–releasing hormone. Although some transsexuals are treated with genital reconstructive surgery, many others are screened out by trial periods of living as the other sex prior to operation.

B. Psychosexual Dysfunction

1. Medical—Identification of a contributory reversible cause is most important. Even if the condition is not reversible, identification of the specific cause helps the patient to accept the condition. Marital disharmony, with its exacerbating effects, may thus be avoided. Of all the sexual dysfunctions, erectile dysfunction is the condition most likely to have an organic basis. Sildenafil, tadalafil, and vardenafil are phosphodiesterase type 5 inhibitors that are effective oral agents for the treatment of penile erectile dysfunction (eg, sildenafil 25–100 mg orally 1 hour prior to intercourse). These agents are effective for SSRI-induced erectile dysfunction in men and in some cases for SSRI-associated sexual dysfunction in women. Use of the medications in conjunction with any nitrates, particularly in individuals with coronary artery disease, can have significant hypotensive effects leading to death in some cases. The medication, which does not appear to impact sexual desire, should be used only once a day. Because of their common effect in delaying ejaculation, the SSRIs have been effective in premature ejaculation.

2. Behavioral—Syndromes resulting from conditioned responses have been treated by conditioning techniques, with excellent results. Vaginismus responds well to desensitization with graduated Hegar dilators along with relaxation techniques. Masters and Johnson have used behavioral approaches in all of the sexual dysfunctions, with concomitant supportive psychotherapy and with improvement of the communication patterns of the couple.

3. Psychological—The use of psychotherapy by itself is best suited for those cases in which interpersonal difficulties or intrapsychic problems predominate. Anxiety and guilt about parental injunctions against sex may contribute to sexual dysfunction. Even in these cases, however, a combined behavioral-psychological approach usually produces results most quickly.

4. Social—The proximity of other people (eg, a mother-in-law) in a household is frequently an inhibiting factor in sexual relationships. In such cases, some social engineering may alleviate the problem.

PERSONALITY DISORDERS

ESSENTIALS OF DIAGNOSIS

- Long history dating back to childhood.
- Recurrent maladaptive behavior.
- Low self-esteem and lack of confidence.
- Minimal introspective ability with a tendency to blame others for all problems.
- Major difficulties with interpersonal relationships or society.
- Depression with anxiety when maladaptive behavior fails.

General Considerations

An individual’s personality structure, or character, is an integral part of self-image. It reflects genetics, interpersonal influences, and recurring patterns of behavior adopted in order to cope with the environment. The classification of subtypes of personality disorders depends on the predominant symptoms and their severity. The most severe disorders—those that bring the patient into greatest conflict with society—tend to be classified as antisocial (psychopathic) or borderline.

Personality disorders can be considered a matrix for some of the more severe psychiatric problems (eg, schizotypal, relating to schizophrenia, and avoidance types, relating to some anxiety disorders).

Classification & Clinical Findings

See Table 25–3.

Differential Diagnosis

Patients with personality disorders tend to show anxiety and depression when pathologic coping mechanisms fail, and their symptoms can be similar to those disorders.
Occasionally, the more severe cases may decompensate into psychosis under stress and mimic other psychotic disorders.

### Treatment

#### A. Social

Social and therapeutic environments such as day hospitals, halfway houses, and self-help communities utilize peer pressures to modify the self-destructive behavior. The patient with a personality disorder often has failed to profit from experience, and difficulties with authority impair the learning experience. The use of peer relationships and the repetition possible in a structured setting of a helpful community enhance the behavioral treatment opportunities and increase learning. When problems are detected early, both the school and the home can serve as foci of intensified social pressure to change the behavior, particularly with the use of behavioral techniques.

#### B. Behavioral

The behavioral techniques used are principally operant conditioning and aversive conditioning. The former simply emphasizes the recognition of acceptable behavior and its reinforcement with praise or other tangible rewards. Aversive responses usually mean punishment, although this can range from a mild rebuke to some specific punitive responses such as deprivation of privileges. Extinction plays a role in that an attempt is made not to respond to inappropriate behavior, and the lack of response eventually causes the person to abandon that type of behavior. Pouting and tantrums, for example, diminish quickly when such behavior elicits no reaction. Dialectical behavioral therapy is a program of individual and group therapy specifically designed for patients with chronic suicidality and borderline personality disorder. It blends mindfulness and a cognitive-behavioral model to address self-awareness, interpersonal functioning, affective lability, and reactions to stress.

#### C. Psychological

Psychological intervention is best conducted in group settings. Group therapy is helpful when specific interpersonal behavior needs to be improved. This mode of treatment also has a place with so-called "acting-out" patients, ie, those who frequently act in an impulsive and inappropriate way. The peer pressure in the group tends to impose restraints on rash behavior. The group also quickly identifies the patient’s types of behavior and helps improve the validity of the patient’s self-assessment, so that the antecedents of unacceptable behavior can be effectively handled, thus decreasing its frequency. Individual therapy should initially be supportive, ie, helping the patient to restabilize and mobilize coping mechanisms. If the individual has the ability to observe his or her own behavior, a longer-term and more introspective therapy may be warranted. The therapist must be able to handle countertransference feelings (which are frequently negative), maintain appropriate boundaries in the relationship (no physical contacts, however well-meaning), and refrain from premature confrontations and interpretations.

#### D. Medical

Hospitalization is indicated in the case of serious suicidal or homicidal danger. In most cases, treatment can be accomplished in the day treatment center or self-help community. Antipsychotics may be required for short periods in conditions that have temporarily decompensated into transient psychoses (eg, olanzapine [2.5–10 mg/d orally], risperidone [0.5–2 mg/d orally], or haloperidol [0.5–2 mg/d orally, split into two doses]). In some cases, these medications are required only for several days and can be

SCHIZOPHRENIA & OTHER PSYCHOTIC DISORDERS

ESSENTIALS OF DIAGNOSIS

- Social withdrawal, usually slowly progressive, often with deterioration in personal care.
- Loss of ego boundaries, with inability to perceive oneself as a separate entity.
- Loose thought associations, often with slowed thinking or overinclusive and rapid shifting from topic to topic.
- Autistic absorption in inner thoughts and frequent sexual or religious preoccupations.
- Auditory hallucinations, often of a derogatory nature.
- Delusions, frequently of a grandiose or persecutory nature.
- Symptoms of at least 6 months’ duration. Frequent additional signs:
  - Flat affect and rapidly alternating mood shifts irrespective of circumstances.
  - Hypersensitivity to environmental stimuli, with a feeling of enhanced sensory awareness.
  - Variability or changeable behavior incongruent with the external environment.
  - Concrete thinking with inability to abstract; inappropriate symbolism.
  - Impaired concentration worsened by hallucinations and delusions.
  - Depersonalization, wherein one behaves like a detached observer of one’s own actions.

General Considerations

The schizophrenic disorders are a group of syndromes manifested by massive disruption of thinking, mood, and overall behavior as well as poor filtering of stimuli. The characterization and nomenclature of the disorders are quite arbitrary and are influenced by sociocultural factors and schools of psychiatric thought.

It is currently believed that the schizophrenic disorders are of multifactorial cause, with genetic, environmental, and neurotransmitter pathophysiologic components. At present, there is no laboratory method for confirming the diagnosis of schizophrenia. There may or may not be a history of a major disruption in the individual’s life (failure, loss, physical illness) before gross psychotic deterioration is evident.

Schizophrenic symptoms have been classified into positive and negative categories. Positive symptoms include hallucinations, delusions, and formal thought disorders; these symptoms appear to be related to increased dopaminergic (D2) activity in the mesolimbic region. Negative symptoms include diminished sociability, restricted affect, and poverty of speech; these symptoms appear to be related to decreased D1 activity in the mesocortical system.

“Other psychotic disorders” are conditions that are similar to schizophrenic disorders in their acute symptoms but have a less pervasive influence over the long term. The patient usually attains higher levels of functioning. The acute psychotic episodes tend to be less disruptive of the person’s lifestyle, with a fairly quick return to previous levels of functioning.

Classification

A. Schizophrenic Disorders

Schizophrenic disorders are subdivided on the basis of certain prominent phenomena that are frequently present. Disorganized (hebephrenic) schizophrenia is characterized by marked incoherence and an incongruous or silly affect. Catatonic schizophrenia is distinguished by a marked psychomotor disturbance of either excitement (purposeless and stereotyped) or rigidity with mutism. Infrequently, there may be rapid alternation between excitement and stupor (see under catatonic syndrome, below). Paranoid schizophrenia includes marked persecutory or grandiose delusions often consonant with hallucinations of similar content and with less marked disorganization of speech and behavior. Undifferentiated schizophrenia denotes a category in which symptoms are not specific enough to warrant inclusion of the illness in the other subtypes. Residual schizophrenia is a classification that includes persons who have clearly had an episode warranting a diagnosis of schizophrenia but who at present have no overt psychotic symptoms, although they show milder signs such as social withdrawal, flat affect, and eccentric behaviors.

B. Delusional Disorders

Delusional disorders are psychoses in which the predominant symptoms are persistent, nonbizarre delusions with

Prognosis

Antisocial and borderline categories generally have a guarded prognosis. Those patients with a history of parental abuse and a family history of mood disorder tend to have the most challenging treatments.

minimal impairment of daily functioning. (The schizophrenic disorders show significant impairment.) Intellectual and occupational activities are little affected, whereas social and marital functioning tend to be markedly involved. Hallucinations are not usually present. Common delusional themes include paranoid delusions of persecution, delusions of being related to or loved by a well-known person, and delusions that one’s partner is unfaithful.

C. Schizoaffective Disorders

Schizoaffective disorders are those cases that fail to fit comfortably either in the schizophrenic or in the affective categories. They are usually cases with affective symptoms that precede or develop concurrently with psychotic manifestations. There has been increasing interest in studying prodromal schizophrenia with a goal of prevention or early treatment.

D. Schizophreniform Disorders

Schizophreniform disorders are similar in their symptoms to schizophrenic disorders except that the duration of prodromal, acute, and residual symptoms is > 1 week but < 6 months.

E. Brief Psychotic Disorders

These disorders last < 1 week. They are the result of psychological stress. The shorter duration is significant and correlates with a more acute onset and resolution as well as a much better prognosis.

F. Late Life Psychosis

Brain abnormalities occur in 40% of patients who develop psychotic symptoms after age 60. The psychotic symptoms are typical, and there are other findings such as low IQ scores and diminished cognitive function.

G. Atypical Psychoses

This group includes a wide range of conditions with psychotic symptoms. The cause is often not clear, but later events (eg, new symptoms) may clarify the diagnosis. The most common example is chronic psychosis developing either during periods of heavy abuse of drugs or at some time after the drug use has ceased. Other conditions include temporal lobe dysfunction, HIV infection, and a number of the conditions noted in the differential diagnosis (see below). They often have a good premorbid history, a precipitous onset, and an episodic course with symptom-free intervals.

Clinical Findings

A. Symptoms and Signs

The symptoms and signs of schizophrenia vary markedly among individuals as well as in the same person at different times. The patient’s appearance may be bizarre, although the usual finding is a mild to moderate unkempt blandness. Motor activity is generally reduced, although extremes ranging from catatonic stupor to frenzied excitement occur. Social behavior is characterized by marked withdrawal coupled with disturbed interpersonal relationships and a reduced ability to experience pleasure. Dependency and a poor self-image are common. Verbal utterances are variable, the language being concrete yet symbolic, with unassociated rambling statements (at times interspersed with mutism) during an acute episode. Neologisms (made-up words or phrases), echolalia (repetition of words spoken by others), and verbigeration (repetition of senseless words or phrases) are occasionally present. Affect is usually flattened, with occasional inappropriateness. Depression is present in almost all cases but may be less apparent during the acute psychotic episode and more obvious during recovery. Depression is sometimes confounded with akinetic side effects of antipsychotic medications. It is also related to boredom, which increases symptoms and decreases the response to treatment. Work is generally unavailable and time unfilled, providing opportunities for counterproductive activities such as drug abuse, withdrawal, and increased psychotic symptoms.

Thought content may vary from a paucity of ideas to a rich complex of delusional fantasy with archaic thinking. One frequently notes after a period of conversation that little if any information has actually been conveyed. Incoming stimuli produce varied responses. In some cases a simple question may trigger explosive outbursts, whereas at other times there may be no overt response whatsoever (catatonia). When paranoid ideation is present, the patient is often irritable and less cooperative. Delusions (false beliefs) are characteristic of paranoid thinking, and they usually take the form of a preoccupation with the supposedly threatening behavior exhibited by other individuals. This ideation may cause the patient to adopt active countermeasures such as locking doors and windows, taking up weapons, covering the ceiling with aluminum foil to counteract radar waves, and other bizarre efforts. Somatic delusions revolve around issues of bodily decay or infestation. Perceptual distortions usually include auditory hallucinations—visual hallucinations are more commonly associated with organic mental states—and may include illusions (distortions of reality) such as figures changing in size or lights varying in intensity. Cenesthetic hallucinations (eg, a burning sensation in the brain, feeling blood flowing in blood vessels) occasionally occur. Lack of humor, feelings of dread, depersonalization (a feeling of being apart from the self), and fears of annihilation may be present. Any of the above symptoms generate higher anxiety levels, with heightened arousal and occasional panic and suicidal ideation, as the individual fails to cope.

The development of the acute episode in schizophrenia frequently is the end product of a gradual decompensation. Frustration and anxiety appear early, followed by depression and alienation, along with progressive ineffectiveness in day-to-day coping. This often leads to feelings of panic and increasing disorganization, with loss of the ability to test and evaluate the reality of perceptions. The stage of so-called psychotic resolution includes delusions, autistic preoccupations, and psychotic insight, with acceptance of the decompensated state. The process is frequently complicated...
by the use of caffeine, alcohol, and other recreational drugs. Life expectancy of schizophrenic patients is as much as 20% shorter than that of cohorts in the general population and is often associated with comorbid conditions such as the metabolic syndrome.

**Polydipsia** may produce water intoxication with hyponatremia—characterized by symptoms of confusion, lethargy, psychosis, seizures, and occasionally death—in any psychiatric disorder, but most commonly in schizophrenia. These problems exacerbate the schizophrenic symptoms and can be confused with them. Possible pathogenetic factors in polydipsia include a hypothalamic defect, inappropriate antidiuretic hormone (ADH) secretion, neuroleptic medications (anticholinergic effects, stimulation of hypothalamic thirst center, effect on ADH), smoking (nicotine and syndrome of inappropriate antidiuretic hormone [SIADH]), psychotic thought processes (delusions), and other medications (eg, diuretics, antidepressants, lithium, alcohol). Other causes of polydipsia must be ruled out (eg, diabetes mellitus, diabetes insipidus, kidney disease).

**B. Imaging**

Ventricular enlargement and cortical atrophy, as seen on CT scan, have been correlated with chronic course, severe cognitive impairment, and nonresponsiveness to neuroleptic medications. Decreased frontal lobe activity seen on PET scan has been associated with negative symptoms.

### Differential Diagnosis

One should not hesitate to reconsider the diagnosis of schizophrenia in any person who has received that diagnosis in the past, particularly when the clinical course has been atypical. A number of these patients have been found to actually have atypical episodic affective disorders that have responded well to lithium. Manic episodes often mimic schizophrenia. Furthermore, schizophrenia has been diagnosed in many individuals because of inadequacies in psychiatric nomenclature. Thus, schizophrenia was often inappropriately diagnosed in persons with brief reactive psychoses, OCD, paranoid disorders, and schizoparamphoriform disorders.

Psychotic depressions, psychotic organic mental states, and any illness with psychotic ideation tend to be confused with schizophrenia, partly because of the regrettable tendency to use the terms interchangeably. Adolescent phases of growth and counterculture behaviors constitute another area of diagnostic confusion. It is particularly important to avoid a misdiagnosis in these groups, because of the long-term implications arising from having such a serious diagnosis made in a formative stage of life.

**Medical disorders** such as thyroid dysfunction, adrenal and pituitary disorders, reactions to toxic materials (eg, mercury, PCBs), and almost all of the organic mental states in the early stages must be ruled out. Postpartum psychosis is discussed under Mood Disorders. **Complex partial seizures**, especially when psychosexual phenomena are present, are an important differential consideration. Toxic drug states arising from prescription, over-the-counter, herbal and street drugs may mimic all of the psychotic disorders.

The chronic use of amphetamines, cocaine, and other stimulants frequently produces a psychosis that is almost identical to the acute paranoid schizophrenic episode. The presence of formation (sensation of insects crawling on or under the skin) and stereotypy suggests the possibility of stimulant abuse. Phencyclidine (see below), a very common street drug, may cause a reaction that is difficult to distinguish from other psychotic disorders. Cerebellar signs, excessive salivation, dilated pupils, and increased deep tendon reflexes should alert the clinician to the possibility of a toxic psychosis. Industrial chemical toxicity (both organic and metallic), degenerative disorders, and metabolic deficiencies must be considered in the differential diagnosis.

**Catatonic syndrome**, frequently assumed to exist solely as a component of schizophrenic disorders, is actually the end product of a number of illnesses, including various organic conditions. Neoplasms, viral and bacterial encephalopathies, central nervous system hemorrhage, metabolic derangements such as diabetic ketoacidosis, sedative withdrawal, and hepatic and renal malfunction have all been implicated. It is particularly important to realize that drug toxicity (eg, overdoses of antipsychotic medications such as fluphenazine or haloperidol) can cause catatonic syndrome, which may be misdiagnosed as a catatonic schizoparamphoriform disorder and inappropriately treated with more antipsychotic medication.

### Treatment

#### A. Medical

Hospitalization is often necessary, particularly when the patient’s behavior shows gross disorganization. The presence of competent family members lessens the need for hospitalization, and each case should be judged individually. The major considerations are to prevent self-inflicted harm or harm to others and to provide the patient’s basic needs. A full medical evaluation and CT scan or MRI of the brain should be considered in first episodes of schizoparamphoriform disorder and other psychotic episodes of unknown cause.

**Antipsychotic medications** (see below) are the treatment of choice. The relapse rate can be reduced by 50% with proper maintenance neuroleptic therapy. Long-acting, injectable depot neuroleptics are used in noncompliant patients or nonresponders to oral medication.

Antipsychotic medications include the “**typical**” neuroleptics phenothiazines, thioxanthenes (both similar in structure), butyrophenones, dihydroindolones, dibenzoazepines, and benzisoxazoles, and the newer “**atypical**” neuroleptics clozapine, risperidone, olanzapine, quetiapine, aripiprazole, ziprasidone, paliperidone, iloperidone, and larusidone (Table 25–4). Generally, increasing milligram potency of the typical neuroleptics is associated with decreasing anticholinergic and adrenergic side effects and increasing extrapyramidal symptoms (Table 25–5). For example, chlorpromazine has lower potency and more severe anticholinergic and adrenergic side effects. The increased anticholinergic effect of chlorpromazine, however, lowers the risk of extrapyramidal symptoms.
The first “atypical” (novel) antipsychotic drug developed, clozapine, a dibenzodiazepine derivative, has dopamine (D4) receptor-blocking activity as well as central serotonergic, histaminergic, and α-noradrenergic receptor-blocking activity. It is effective in the treatment of about 30% of psychoses resistant to other neuroleptic medications. Research suggests that clozapine may have specific efficacy in decreasing suicidality in patients with schizophrenia. It is associated with a 1% risk of agranulocytosis, which requires weekly white blood cell count monitoring for the first 6 months followed by monitoring every other week. Weekly monitoring for 1 month after discontinuation of the medication is recommended. Because of an association between clozapine and myocarditis, the drug is contraindicated in patients with severe heart disease. Risperidone is an antipsychotic that blocks some serotonin receptors (5-HT2) and dopamine receptors (D2). Risperidone causes fewer extrapyramidal side effects than the typical antipsychotics at doses < 6 mg.

The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study compared “atypical” and “typical” neuroleptic medications. Although it was not definitive, it suggested similar antipsychotic efficacy for both classes and a tendency for the atypicals, particularly olanzapine, to be better tolerated leading to enhanced compliance. It also highlighted lack of patient adherence as a major factor in treatments.

The phenothiazines comprise the bulk of the currently used “typical” neuroleptic medications. The only butyrophenone commonly used in psychiatry is haloperidol, which is different in structure but similar in action and side effects to the piperazine phenothiazines such as fluphenazine, perphenazine, and trifluoperazine. These medications and haloperidol (dopamine [D2] receptor blockers) have high potency and a paucity of autonomic side effects and act to markedly lower arousal levels. Molindone and loxapine, while less potent, are similar in action, side effects, and safety to the piperazine phenothiazines.
Olanzapine is a potent blocker of muscarinic, anticholinergic, 5-HT₂, and dopamine D₁, D₂, and D₄ receptors. High doses of olanzapine (12.5–17.5 mg daily) appear to be more effective than lower doses. The drug appears to be more effective than haloperidol in the treatment of negative symptoms, such as withdrawal, psychomotor retardation, and poor interpersonal relationships. It is available in an orally disintegrating form for patients who are unable to tolerate standard oral dosing and in an injectable form for the management of acute agitation associated with schizophrenia and bipolar disorder. Olanzapine tends to result in elevations of serum alanine aminotransferase more commonly than does haloperidol. Olanzapine is associated with a much lower incidence of dystonic reaction than haloperidol and is perhaps less likely to induce tardive dyskinesia. Its most common side effects include somnolence, agitation, nervousness, headache, insomnia, dizziness, and significant weight gain. Multiple case reports have linked olanzapine and clozapine to new-onset type 2 diabetes, and all atypical medications should be monitored for this adverse effect as well. The manufacturer has alerted physicians to an association between olanzapine and a significantly higher risk of stroke and death in elderly patients, which has also been noted with other atypical and typical agents (see below).

Quetiapine is a neuroleptic with greater 5-HT₂ relative to D₂ receptor blockade as well as a relatively high affinity for α₁- and α₂-adrenergic receptors. It appears to be as efficacious as haloperidol in treating positive and negative symptoms of schizophrenia, with less extrapyramidal side effects even at high doses. More common side effects include somnolence, dizziness, and postural hypotension. Because of an association with lens changes seen in patients on long-term treatment, an eye examination to detect cataract formation is recommended at initiation of treatment and then at 6-month intervals during treatment. Quetiapine may cause QT prolongation particularly when prescribed with other medications that effect the QT interval and in overdose.

Risperidone-induced hyperprolactinemia, even on low doses, has been reported, and that effect is thought to be more common with risperidone than with other atypical antipsychotics. Risperidone is available in a long-acting injectable preparation.

Ziprasidone has both anti-dopamine receptor and anti-serotonin receptor effects, with good efficacy for both positive and negative symptoms of schizophrenia, with less extrapyramidal side effects even at high doses. More common side effects include somnolence, dizziness, and postural hypotension. Because of an association with lens changes seen in patients on long-term treatment, an eye examination to detect cataract formation is recommended at initiation of treatment and then at 6-month intervals during treatment. Quetiapine may cause QT prolongation particularly when prescribed with other medications that effect the QT interval and in overdose.

Ziprasidone has both anti-dopamine receptor and anti-serotonin receptor effects, with good efficacy for both positive and negative symptoms of schizophrenia, with less extrapyramidal side effects even at high doses. More common side effects include somnolence, dizziness, and postural hypotension. Because of an association with lens changes seen in patients on long-term treatment, an eye examination to detect cataract formation is recommended at initiation of treatment and then at 6-month intervals during treatment. Quetiapine may cause QT prolongation particularly when prescribed with other medications that effect the QT interval and in overdose.

It appears to be as effective as haloperidol and possibly as effective as clozapine in treatment-resistant patients without requiring weekly white cell counts. Risperidone-induced hyperprolactinemia, even on low doses, has been reported, and that effect is thought to be more common with risperidone than with other atypical antipsychotics. Risperidone is available in a long-acting injectable preparation.

Table 25–5. Relative potency and side effects of antipsychotic medications.
overdose there were no incidents of torsades de pointes or sudden death. Patients taking ziprasidone should be screened for cardiac risk factors. A pretreatment ECG is indicated for patients at risk for cardiac sequelae (including patients taking other medications that might prolong the QTc interval).

Ziprasidone is a dopamine D2 and serotonin 5-HT1 receptor antagonist and an antagonist at 5-HT2, receptors, it is effective against positive and negative symptoms of schizophrenia. It functions as an antagonist or agonist, depending on the dopaminergic activity at the dopamine receptors. This may help decrease side effects. More activating than sedating, ziprasidone is thought to impose a low risk of extrapyramidal symptoms, weight gain, hyperprolactinemia, and delayed QT interval. Ziprasidone has been approved as an augmentation agent for treatment-resistant depression even when psychosis is not present. Aripiprazole, is available as a capsule and a monthly injection.

It has the advantage of low associations with diabetes melitus, weight gain, and dyslipidemia. Both aripiprazole and paliperidone increase the risk of QT interval prolongation and should be avoided in patients with risk factors for this ECG finding. Asenapine can cause hyperprolactinemia and weight gain. Asenapine carries a warning of possible serious allergic reaction, even after the first dose including anaphylaxis, low blood pressure, and difficulty breathing. Patients should be appropriately cautioned. Iloperidone has low incidence of extrapyramidal side effects that is similar to the other atypical agents but requires careful initial titration due to the risk of orthostatic hypotension and possibility of lengthening the QT interval. When coadministered with paroxetine or clorazepate, the dose of iloperidone must be halved because of decreased hepatic metabolism by the cytochrome P450 CYP2D6 and CYP3A4 isozymes. Lurasidone, approved by the FDA in 2011 has been shown to be effective in treating acute decompensation in patients with chronic schizophrenia. This medication is distinguished by low incidence of weight gain, increased lipids or prolonged QT interval, but clinicians should be mindful of side effects of akathisia, elevated prolactin and in higher doses, somnolence. None of the antipsychotics produce true physical dependency. All decrease adrenergic responses. Despite higher costs, atypical neuroleptics are often considered preferable to traditional antipsychotics because they are thought to be associated with reduced extrapyramidal symptoms and a lesser risk of tardive dyskinesia.

**Clinical Indications**

The antipsychotics are used to treat all forms of the schizophrenias as well as psychotic ideation in organic brain psychoses, delirium and dementia, drug-induced psychoses, psychotic depression, and mania. They are also effective in Tourette disorder. They quickly lower the arousal (activity) level and, perhaps indirectly, gradually improve socialization and thinking. The improvement rate is about 80%. Patients whose behavioral symptoms worsen with use of antipsychotic medications may have an undiagnosed organic condition such as anticholinergic toxicity.

Symptoms that are ameliorated by these medications include hyperactivity, hostility, aggression, delusions, hallucinations, irritability, and poor sleep. Individuals with acute psychosis and good premorbid function respond quite well. The most common cause of failure in the treatment of acute psychosis is inadequate dosage, and the most common cause of relapse is noncompliance.

Although typical antipsychotics are efficacious in the treatment of positive symptoms of schizophrenia, such as hallucinations and delusions, atypical antipsychotics are thought to have efficacy in reducing both positive and negative symptoms. Antidepressant medications may be used in conjunction with neuroleptics if significant depression is present. Resistant cases may require concomitant use of lithium, carbamazepine, or valproic acid. The addition of a benzodiazepine drug to the neuroleptic regimen may prove helpful in treating the agitated or catatonic psychotic patient who has not responded to neuroleptics alone—lorazepam, 1–2 mg orally, can produce a rapid resolution of catatonic symptoms and may allow maintenance with a lower neuroleptic dose. Electroconvulsive therapy (ECT) has also been effective in treating catatonia.

**Dosage Forms & Patterns**

The dosage range is quite broad. For example, risperidone, 0.25–1 mg orally at bedtime, may be sufficient for the elderly person with mild dementia with psychosis (especially in view of the increased risk of stroke and death in the elderly), whereas up to 6 mg/d may be used in a young patient with acute schizophrenia. For quick response, an atypical antipsychotic may be started in combination with a benzodiazepine (eg, risperidone oral solution, 2 mg, or olanzapine, 10 mg orally, and lorazepam, 2 mg orally, every 2–4 hours as needed). In an acutely distressed, psychotic patient one might use haloperidol, 10 mg intramuscularly, which is absorbed rapidly and achieves an initial tenfold plasma level advantage over equal oral doses. Psychomotor agitation, racing thoughts, and general arousal are quickly reduced. The dose can be repeated every 3–4 hours; when the patient is less symptomatic, oral doses can replace parenteral administration in most cases. In the elderly, both atypical (eg, risperidone 0.25 mg–0.5 mg daily or olanzapine 1.25 mg daily) and typical (eg haloperidol 0.5 mg daily or perphenazine 2 mg daily) antipsychotics, often used effectively in small doses for behavioral control, have been linked to premature death in some cases.

Absorption of oral medications may be increased or decreased by concomitant administration of other medications (eg, antacids tend to decrease the absorption of
antidepressants). Previous gastrointestinal surgery may alter pH, motility, and surface areas available for drug absorption. There are racial differences in metabolizing the neuroleptic medications—eg, many Asians require only about half the usual dosage. Bioavailability is influenced by other factors such as smoking or hepatic microsomal enzyme stimulation with alcohol or barbiturates and enzyme-altering medications such as carbamazepine or methylphenidate. Neuroleptic plasma drug level determinations are not currently of major clinical assistance.

Divided daily doses are not necessary after a maintenance dose has been established, and most patients can then be maintained on a single daily dose, usually taken at bedtime. This is particularly appropriate in a case where the sedative effect of the drug is desired for nighttime sleep, and undesirable sedative effects can be avoided during the day. Risperidone is an exception, being given twice daily. First-episode patients especially should be tapered off medications after about 6 months of stability and carefully monitored; their rate of relapse is lower than that of multiple-episode patients.

Psychiatric patients—particularly paranoid individuals—often neglect to take their medication. In these cases and in nonresponders to oral medication, the enanthate and decanoate (the latter is slightly longer-lasting and has fewer extrapyramidal side effects) forms of fluphenazine or the decanoate form of haloperidol may be given by deep subcutaneous injection or intramuscularly to achieve an effect that will usually last 7–28 days. A patient who cannot be depended on to take oral medication (or who overdoes on minimal provocation) will generally agree to come to the clinician’s office for a “shot.” The usual dose of the fluphenazine long-acting preparations is 25 mg every 2 weeks. Dosage and frequency of administration vary from about 100 mg weekly to 12.5 mg monthly. Use the smallest effective amount as infrequently as possible. A monthly injection of 25 mg of fluphenazine decanoate is equivalent to about 15–20 mg of oral fluphenazine daily. Risperidone is the first atypical neuroleptic available in a long-acting injectable form (25–50 mg intramuscularly every 2 weeks). Concomitant use of a benzodiazepine (eg, lorazepam, 2 mg orally twice daily) may permit reduction of the required dosage of oral or parenteral antipsychotic drug.

Intravenous haloperidol, the neuroleptic most commonly used by this route, is often used in critical care units in the management of agitated, delirious patients. Intravenous haloperidol should be given no faster than 1 mg/min to reduce cardiovascular side effects, such as torsades de pointes. Current practice indicates that ECG monitoring should be used whenever haloperidol is being administered intravenously.

### Side Effects

For both typical and atypical neuroleptic agents, a range of side effects has been reported. The most common anticholinergic side effects include **dry mouth** (which can lead to ingestion of caloric liquids and weight gain or hyponatremia), **blurred near vision**, **urinary retention** (particularly in elderly men with enlarged prostates), **delayed gastric emptying**, **esophageal reflux**, **ileus**, **delirium**, and precipitation of **acute glaucoma** in patients with narrow anterior chamber angles. Other autonomic effects include **orthostatic hypotension** and **sexual dysfunction**—problems in achieving erection, ejaculation (including retrograde ejaculation), and orgasm in men (approximately 50% of cases) and women (approximately 30%). Delay in achieving orgasm is often a factor in medication noncompliance. **Electrocardiographic changes** occur frequently, but clinically significant arrhythmias are much less common. Elderly patients and those with preexisting cardiac disease are at greater risk. The most frequently seen electrocardiographic changes include diminution of the T wave amplitude, appearance of prominent U waves, depression of the ST segment, and prolongation of the QT interval. Thioridazine has been given an FDA warning for dose-related QTc delay and risk of fatal cardiac arrhythmias. As noted above, ziprasidone can produce QTc prolongation. An ECG prior to treatment in some patients may be indicated. In some critical care patients, torsades de pointes has been associated with the use of high-dose intravenous haloperidol (usually >30 mg/24 h).

Associations have been suggested between the atypical neuroleptics and **new-onset diabetes, hyperlipidemia, QTc prolongation, and weight gain** (Table 25–6). The FDA has particularly noted the risk of hyperglycemia and new-onset diabetes in this class of medication that is not related to weight gain. The risk of diabetes mellitus is increased in patients taking clozapine and olanzapine. Monitoring of weight, fasting blood sugar and lipids prior to initiation of treatment and at regular intervals thereafter is an important part of medication monitoring. Early research suggests that the addition of metformin to olanzapine may improve drug-induced weight gain in patients with drug-naïve, first-episode schizophrenia. Neuroleptic medications in general may have **metabolic and endocrine effects**, including weight gain, hyperglycemia, impaired temperature regulation in hot weather, and water intoxication, that may be due to inappropriate ADH secretion. Lactation and menstrual irregularities are common (antipsychotic medications should be avoided, if possible, in breast cancer patients because of potential trophic effects of elevated prolactin levels on the breast). Both antipsychotic and antidepressant medications inhibit sperm motility. **Bone marrow depression** and **cholestatic jaundice** occur rarely; these are hypersensitivity reactions, and they usually appear in the first 2 months of treatment. They subside on discontinuance of the drug. There is cross-sensitivity among all of the phenothiazines, and a drug from a different group should be used when allergic reactions occur.

Clozapine is associated with a 1.6% risk of **agranulocytosis** (higher in persons of Ashkenazi Jewish ancestry), and its use must be strictly monitored with weekly blood counts during the first 6 months of treatment, with monitoring every other week thereafter. Discontinuation of the medication requires weekly monitoring of the white blood cell count for 1 month. Clozapine has been associated with
fluid support. Dopamine agonists such as bromocriptine, treatment includes controlling fever and providing hydration, and increased sensitivity of dopamine receptor sites. Lithium in combination with a neuroleptic drug may increase vulnerability, which is already increased in patients with severe heart disease. In addition, clozapine lowers the seizure threshold and has many side effects, including sedation, hypotension, increased liver enzyme levels, hypersalivation, respiratory arrest, weight gain, and changes in both the ECG and the electroencephalogram.

Photosensitivity, retinopathy, and hyperpigmentation are associated with use of fairly high dosages of chlorpromazine and thioridazine. The appearance of particulate melanin deposits in the lens of the eye is related to the total dose given, and patients on long-term medication should have periodic eye examinations. Teratogenicity has not been causally related to these medications, but prudence is indicated particularly in the first trimester of pregnancy. The seizure threshold is lowered, but it is safe to use these medications in epileptics who take anticonvulsants.

The neuroleptic malignant syndrome (NMS) is a catatonia-like state manifested by extrapyramidal signs, blood pressure changes, altered consciousness, and hyperpyrexia; it is an uncommon but serious complication of neuroleptic treatment. Muscle rigidity, involuntary movements, confusion, dysarthria, and dysphagia are accompanied by pallor, cardiovascular instability, fever, pulmonary congestion, and diaphoresis and may result in stupor, coma, and death. The cause may be related to a number of factors, including poor dosage control of neuroleptic medication, affective illness, decreased serum iron, dehydration, and increased sensitivity of dopamine receptor sites. Lithium in combination with a neuroleptic drug may increase vulnerability, which is already increased in patients with an affective disorder. In most cases, the symptoms develop within the first 2 weeks of antipsychotic drug treatment. The syndrome may occur with small doses of the medications. Intramuscular administration is a risk factor. Elevated creatine kinase and leukocytosis with a shift to the left are present early in about half of cases. Treatment includes controlling fever and providing fluid support. Dopamine agonists such as bromocriptine, 2.5–10 mg orally three times a day, and amantadine, 100–200 mg orally twice a day, have also been useful. Dantrolene, 50 mg intravenously as needed, is used to alleviate rigidity (do not exceed 10 mg/kg/d due to hepatotoxicity risk). There is ongoing controversy about the efficacy of these three agents as well as the use of calcium channel blockers and benzodiazepines. ECT has been used effectively in resistant cases. Clozapine has been used with relative safety and fair success as an antipsychotic drug for patients who have had NMS. The syndrome must be differentiated from acute lethal catatonia, malignant hyperthermia, neurotoxic syndromes (including AIDS), and a variety of other conditions such as viral encephalitis, Wilson disease, central anticholinergic syndrome, and hypertonic states (eg, tetany, strychnine poisoning).

Akathisia is the most common (about 20%) extrapyramidal symptom. It usually occurs early in treatment (but may persist after neuroleptics are discontinued) and is frequently mistaken for anxiety or exacerbation of psychosis. It is characterized by a subjective desire to be in constant motion followed by an inability to sit or stand still and consequent pacing. It may induce suicidality or feelings of fright, rage, terror, or sexual torment. Insomnia is often present. It is crucial to educate patients in advance about these potential side effects so that the patients do not misinterpret them as signs of increased illness. In all cases, reevaluate the dosage requirement or the type of neuroleptic drug. One should inquire also about cigarette smoking, which in women has been associated with an increased incidence of akathisia. Antiparkinsonism medications (such as trihexyphenidyl, 2–5 mg orally three times daily) may be helpful, but first-line treatment often includes a benzodiazepine (such as clonazepam 0.5–1 mg orally three times daily). In resistant cases, symptoms may be alleviated by propranolol, 30–80 mg/d orally, diazepam, 5 mg orally three times daily, or amantadine, 100 mg orally three times daily.

Acute dystonias usually occur early, although a late (tardive) occurrence is reported in patients (mostly men

1QTc prolongation is a side effect of many medications and suggests a possible risk for arrhythmia. Prescriber’s Letter 2011; 18(12):271207.
after several years of therapy) who previously had early severe dystonic reactions and a mood disorder (see below). Younger patients are at higher risk for acute dystonias. The most common signs are bizarre muscle spasms of the head, neck, and tongue. Frequently present are torticollis, oculogyric crises, swallowing or chewing difficulties, and masseter spasms. Laryngospasm is particularly dangerous. Back, arm, or leg muscle spasms are occasionally reported. Diphenhydramine, 50 mg intramuscularly, is effective for the acute crisis; one should then give benztropine mesylate, 2 mg orally twice daily, for several weeks, and then discontinue gradually, since few of the extrapyramidal symptoms require long-term use of the antiparkinsonism medications (all of which are about equally efficacious—though trihexyphenidyl tends to be mildly stimulating and benztropine mildly sedating).

**Drug-induced parkinsonism** is indistinguishable from idiopathic parkinsonism, but it is reversible, occurs later in treatment than the preceding extrapyramidal symptoms, and in some cases appears after neuroleptic withdrawal. The condition includes the typical signs of apathy and reduction of facial and arm movements (akinesia, which can mimic depression), festinating gait, rigidity, loss of postural reflexes, and pill-rolling tremor. AIDS patients seem particularly vulnerable to extrapyramidal side effects. High-potency neuroleptics often require antiparkinsonism medications (see Table 24–6). The neuroleptic dosage should be reduced, and immediate relief can be achieved with antiparkinsonism medications in the same dosages as above. After 4–6 weeks, these antiparkinsonism medications can often be discontinued with no recurrent symptoms. In any of the extrapyramidal symptoms, amantadine, 100–400 mg orally daily, may be used instead of the antiparkinsonism medications. Neuroleptic-induced catatonia is similar to catatonic stupor with rigidity, drooling, urinary incontinence, and cogwheeling. It usually responds slowly to withdrawal of the offending medication and use of antiparkinsonism agents.

**Tardive dyskinesia** is a syndrome of abnormal involuntary stereotyped movements of the face, mouth, tongue, trunk, and limbs that may occur after months or (usually) years of treatment with neuroleptic agents. The syndrome affects 20–35% of patients who have undergone long-term neuroleptic therapy. Predisposing factors include older age, many years of treatment, cigarette smoking, and diabetes mellitus. Pineal calcification is higher in this condition by a margin of 3:1. There are no clearcut differences among the antipsychotic medications in the development of tardive dyskinesia. (Although the atypical antipsychotics appear to offer a lesser risk of tardive dyskinesia, long-term effects have not been investigated.) Early manifestations of tardive dyskinesia include fine worm-like movements of the tongue at rest, difficulty in sticking out the tongue, facial tics, increased blink frequency, or jaw movements of recent onset. Later manifestations may include bucco-linguo-masticatory movements, lip smacking, chewing motions, mouth opening and closing, disturbed gag reflex, puffing of the cheeks, disrupted speech, respiratory distress, or choreoathetoid movements of the extremities (the last being more prevalent in younger patients). The symptoms do not necessarily worsen and in rare cases may lessen even though neuroleptic medications are continued. The dyskinesias do not occur during sleep and can be voluntarily suppressed for short periods. Stress and movements in other parts of the body will often aggravate the condition.

Early signs of dyskinesia must be differentiated from those reversible signs produced by ill-fitting dentures or nonneuroleptic medications such as levodopa, TCAs, antiparkinsonism agents, anticonvulsants, and antihistamines. Other neurologic conditions such as Huntington chorea can be differentiated by history and examination. The emphasis should be on prevention of side effects. Use the least amount of neuroleptic drug necessary to mute the psychotic symptoms, and use atypical antipsychotics as first line agents. Detect early manifestations of dyskinesias. When these occur, stop anticholinergic medications and gradually discontinue neuroleptic medications, if clinically feasible. Weight loss and cachexia sometimes appear on withdrawal of neuroleptics. In an indeterminate number of cases, the dyskinesias will remit. Keep the patient off the medications until reemergent psychotic symptoms dictate their resumption, at which point they are restarted in low doses and gradually increased until there is clinical improvement. If neuroleptic medications are restarted, clozapine and olanzapine appear to offer less risk of recurrence. The use of adjunctive agents such as benzodiazepines or lithium may help directly or indirectly by allowing control of psychotic symptoms with a low dosage of neuroleptics. If the dyskinetic syndrome recurs and it is necessary to continue neuroleptic medications to control psychotic symptoms, informed consent should be obtained. Benzodiazepines, buspirone (in doses of 15–60 mg/d orally), phosphatidylcholine, clonidine, calcium channel blockers, vitamin E, omega-3 fatty acids, and propranolol all have had limited usefulness in treating the dyskinetic side effects.

### B. Social

Environmental considerations are most important in the individual with a chronic illness, who usually has a history of repeated hospitalizations, a continued low level of functioning, and symptoms that never completely remit. Family rejection and work failure are common. In these cases, board and care homes staffed by personnel experienced in caring for psychiatric patients are most important. There is frequently an inverse relationship between stability of the living situation and the amounts of required antipsychotic medications, since the most salutary environment is one that reduces stimuli. Nonresidential self-help groups such as Recovery, Inc., should be utilized whenever possible. They provide a setting for sharing, learning, and mutual support and are frequently the only social involvement with which this type of patient is comfortable. Vocational rehabilitation and work agencies (eg, Goodwill Industries, Inc.) provide assessment, training, and job opportunities at a level commensurate with the person’s clinical condition.
The need for psychotherapy varies markedly depending on the patient’s current status and history. In a person with a single psychotic episode and a previously good level of adjustment, supportive psychotherapy may help the patient reintegrate the experience, gain some insight into antecedent problems, and become a more self-observing individual who can recognize early signs of stress. Insight-oriented psychotherapy is often counterproductive in this type of disorder. Research suggests that cognitive behavioral therapy—in conjunction with medication management—may have some efficacy in the treatment of symptoms of schizophrenia. Cognitive behavioral therapy for schizophrenia involves helping the individual challenge psychotic thinking and alters response to hallucinations. Similarly, a form of psychotherapy called acceptance and commitment therapy has shown value in helping prevent hospitalizations in schizophrenia. Cognitive remediation therapy is another approach to treatment that shows promise in helping schizophrenics become better able to focus their disorganized thinking. Family therapy may also help alleviate the patient’s stress and to assist relatives in coping with the patient.

Behavioral techniques (see above) are most frequently used in therapeutic settings such as day treatment centers, but there is no reason why they cannot be incorporated into family situations or any therapeutic setting. Many behavioral techniques (eg, positive reinforcement—whether it be a word of praise or an approving nod—afer some positive behavior), can be a powerful instrument for helping a person learn behaviors that will facilitate social acceptance. Music from portable digital players with earphones is one of many ways to divert the patient’s attention from auditory hallucinations.

Prognosis

In any psychosis, in the large majority of patients the prognosis is excellent for alleviation of positive symptoms such as hallucinations or delusions treated with medication. Negative symptoms such as diminished affect and sociability are much more difficult to treat but appear responsive to atypical antipsychotics. Unavailability of structured work situations and lack of family therapy are two other reasons why the prognosis is so guarded in such a large percentage of schizophrenic patients. Psychosis connected with a history of serious drug abuse has a guarded prognosis because of the central nervous system damage, usually from the medications themselves and associated medical illnesses.

Clinical Findings

In general, there are four major types of depressions, with similar symptoms in each group.

A. Adjustment Disorder with Depressed Mood

Depression may occur in reaction to some identifiable stressor or adverse life situation, usually loss of a person by death (grief reaction), divorce, etc; financial reversal (crisis); or loss of an established role, such as being needed. Anger is frequently associated with the loss, and this in turn often produces a feeling of guilt. The disorder occurs within 3 months of the stressor and causes significant impairment in social or occupational functioning. The symptoms range from mild sadness, anxiety, irritability, worry, lack of concentration, discouragement, and somatic complaints to the more severe symptoms of frank depression. When the full criteria for major depressive disorder are present (see below), then that diagnosis should be made and treatment instituted even when there is a known stressor. The presence of a stressor is not the determining diagnostic driver, it is the resultant syndromal complex. One should not neglect treatment for major depression simply because it may appear to be an understandable reaction to a particular stress or difficulty.

B. Depressive Disorders

The subclassifications include major depressive disorder and dysthymia.

1. Major depressive disorder—A major depressive disorder (eg, “endogenous” unipolar disorder, melancholia) consists of at least one episode of serious mood depression that occurs at any time of life. Many consider a physiologic or metabolic aberration to be causative. Complaints vary widely but most frequently include a loss of interest and pleasure (anhedonia), withdrawal from activities, and feelings of guilt. Also included are inability to concentrate, some cognitive dysfunction, anxiety, irritability, chronic fatigue, feelings of worthlessness, somatic complaints (unexplained somatic complaints frequently indicate depression), loss of sexual drive, and thoughts of death. Diurnal variation with improvement as the day progresses is common. Vegetative signs that frequently occur are insomnia, anorexia with weight loss, and constipation. Occasionally, severe agitation and psychotic ideation (paranoid thinking, somatic delusions) are present. These symptoms are more common in depressed persons who are older than 50 years. Paranoid symptoms may range from general suspiciousness to ideas of reference with delusions. The somatic delusions frequently revolve around feelings of impending annihilation or hypochondriacal beliefs (eg, that the body is rotting away with cancer). Hallucinations are uncommon.

Subcategories include major depression with atypical features characterized by hypersomnia, overeating, lethargy, and rejection sensitivity. Major depression with a seasonal onset (seasonal affective disorder) is a dysfunction of circadian rhythms that occurs more commonly in the winter months and is believed to be due to decreased exposure to full-spectrum light. Common symptoms include carbohydrate craving, lethargy, hyperphagia, and hypersomnia. Major depression with postpartum onset usually occurs 2 weeks to 6 months postpartum. Most women (up to 80%) experience some mild letdown of mood in the postpartum period. For some of these (10–15%), the symptoms are more severe and similar to those usually seen in serious depression, with an increased emphasis on concerns related to the baby (obsessive thoughts about harming it or inability to care for it). When psychotic symptoms occur, there is frequently associated sleep deprivation, volatility of behavior, and manic-like symptoms. Postpartum psychosis is much less common (<2%), often occurs within the first 2 weeks, and requires early and aggressive management. Biologic vulnerability with hormonal changes and psychosocial stressors all play a role. The chances of a second episode are about 25% and may be reduced with prophylactic treatment.

2. Dysthymia—Dysthymia is a chronic depressive disturbance. Sadness, loss of interest, and withdrawal from activities over a period of 2 or more years with a relatively persistent course is necessary for this diagnosis. Generally, the symptoms are milder but longer-lasting than those in a major depressive episode.

3. Premenstrual dysphoric disorder—Depressive symptoms occur during the late luteal phase (last 2 weeks) of the menstrual cycle. (See also chapter 18)

C. Bipolar Disorders

Bipolar disorders consist of episodic mood shifts into mania, major depression, hypomania, and mixed mood states. The ability of bipolar disorder to mimic aspects of many other coincident major mental health disorders and a high comorbidity with substance abuse can make the initial diagnosis of bipolar disorder difficult. Bipolar I is diagnosed when an individual has both depressive and manic episodes. For individuals who experience depressive and hypomanic episodes without frank mania, the diagnosis would be Bipolar II. Individuals who become manic when treated with an antidepressant for a depressive episode are often regarded as Bipolar III.

1. Mania—A manic episode is a mood change characterized by elation with hyperactivity, overinvolvement in life activities, increased irritability, flight of ideas, easy distractibility, and little need for sleep. The overenthusiastic quality of the mood and the expansive behavior initially attract others, but the irritability, mood lability with swings into depression, aggressive behavior, and grandiosity usually lead to marked interpersonal difficulties. Activities may occur that are later regretted, eg, excessive spending, resignment from a job, a hasty marriage, sexual acting out, and exhibitionistic behavior, with alienation of friends and family. Atypical manic episodes can include gross delusions, paranoid ideation of severe proportions, and auditory hallucinations usually related to some grandiose perception. The episodes begin abruptly (sometimes precipitated by life stresses) and may last from several days to months. Spring and summer tend to be the peak periods.
Generally, the manic episodes are of shorter duration than the depressive episodes. In almost all cases, the manic episode is part of a broader bipolar (manic-depressive) disorder. Patients with four or more discrete episodes of a mood disturbance in 1 year are called “rapid cyclers.” (Substance abuse, particularly cocaine, can mimic rapid cycling.) These patients have a higher incidence of hypothyroidism. Manic patients differ from patients with schizophrenia in that the former use more effective interpersonal maneuvers, are more sensitive to the social maneuvers of others, and are more able to utilize weakness and vulnerability in others to their own advantage. Creativity has been positively correlated with mood disorders, but the best work done is between episodes of mania and depression.

2. Cyclothymic disorders—These are chronic mood disturbances with episodes of depression and hypomania. The symptoms must have at least a 2-year duration and are milder than those that occur in depressive or manic episodes. Occasionally, the symptoms will escalate into a full-blown manic or depressive episode, in which case reclassification as bipolar I would be warranted.

### D. Mood Disorders Secondary to Illness and Medications

Any illness, severe or mild, can cause significant depression. Conditions such as rheumatoid arthritis, multiple sclerosis, stroke, and chronic heart disease are particularly likely to be associated with depression, as are other chronic illnesses. Depression is common in cancer, as well, with a particularly high degree of comorbidity in pancreatic cancer. Hormonal variations clearly play a role in some depressions. Varying degrees of depression occur at various times in schizophrenic disorders, central nervous system disease, and organic mental states. Alcohol dependency frequently coexists with serious depression.

The classic model of drug-induced depression occurs with the use of reserpine, both in clinical settings and as a pharmacologic probe in research settings. Corticosteroids and oral contraceptives are commonly associated with affective changes. Antihypertensive medications such as methyldopa, guanethidine, and clonidine have been associated with the development of depressive syndromes, as have digitalis and antiparkinsonism medications (eg, levodopa). Interferons are strongly associated with depressed mood as a side effect; consultation with a psychiatrist prior to prescribing these agents is indicated in cases where there is a history of depression. It is unusual for \( \beta \)-blockers to produce depression when given for short periods, such as in the treatment of performance anxiety. Sustained use of \( \beta \)-blockers for medical conditions such as hypertension may produce depression in some patients, although most individuals do not suffer this adverse effect and the data supporting this association remain inconclusive. Infrequently, disulfiram and anticholinesterase medications may be associated with symptoms of depression. All stimulant use results in a depressive syndrome when the drug is withdrawn. Alcohol, sedatives, opiates, and most of the psychedelic drugs are depressants and, paradoxically, are often used in self-treatment of depression.

### Differential Diagnosis

Since depression may be a part of any illness—either reactively or as a secondary symptom—careful attention must be given to personal life adjustment problems and the role of medications (eg, reserpine, corticosteroids, levodopa). Schizophrenia, partial complex seizures, organic brain syndromes, panic disorders, and anxiety disorders must be differentiated. Subtle thyroid dysfunction must be ruled out.

### Complications

The most important complication is suicide, which often includes some elements of aggression. Suicide rates in the general population vary from 9 per 100,000 in Spain to 20 per 100,000 in the United States to 58 per 100,000 in Hungary. In individuals with depression, the lifetime risk rises to 10–15%. In patients with bipolar disorder, the risk is higher, with up to 20% of individuals dying of suicide. Men tend toward successful suicide, particularly in older age groups, whereas women make more attempts with lower mortality rates. An increased suicide rate is being observed in the younger population, ages 15–35. Patients with cancer, respiratory illnesses, AIDS, and those being maintained on hemodialysis have higher suicide rates. Alcohol use is a significant factor in many suicide attempts.

There are several groups of people who make suicide attempts. One group includes those individuals with acute situational problems. These individuals may be acutely distressed by a recent breakup in a relationship or another type of disappointment. This group also includes those who may not be diagnosed as having depression but who are overwhelmed by a stressful situation often with an aspect of public humiliation (eg, the man charged with child molestation who hangs himself in his cell). A suicide attempt in such cases may be an impulsive or aggressive act not associated with significant depression. In such cases, a suicide attempt is clearly a stratagem for controlling or hurting others or an attempted escape.

Another high-risk group includes individuals with severe depression. Severe depression may be due to conditions such as medical illness (eg, AIDS, whose victims have a suicide rate over 20 times that of the general population) or comorbid psychiatric disorders (eg, panic disorders). Anxiety, panic, and fear are major findings in suicidal behavior. A patient may seem to make a dramatic improvement, but the lifting of depression may be due to the patient’s decision to commit suicide. Another high-risk group are individuals with psychotic illness who tend not to verbalize their concerns, are unpredictable, and are often successful in their suicide attempt, although they make up only a small percentage of the total.

Finally, suicide is 10 times more prevalent in patients with schizophrenia than in the general population, and jumping from bridges is a more common means of attempted suicide by schizophrenics than by others. In one study of 100 “jumpers,” 47% had schizophrenia.

The immediate goal of psychiatric evaluation is to assess the current suicidal risk and the need for hospitalization versus outpatient management. Perhaps the one most useful question is to ask the person how many hours per
day he or she thinks about suicide. If it is more than 1 hour, the individual is at high risk. Further assessing the risk by inquiring about intent, plans, means, and suicide-inhibiting factors (eg, strong ties to children or the church) is essential. The intent is less likely to be truly suicidal, for example, if small amounts of poison or medication were ingested or scratching of wrists was superficial, if the act was performed in the vicinity of others or with early notification of others, or if the attempt was arranged so that early detection would be anticipated. Alcohol, hopelessness, delusional thoughts, and complete or nearly complete loss of interest in life or ability to experience pleasure are all positively correlated with suicide attempts. Other risk factors are previous attempts, a family history of suicide, medical or psychiatric illness (eg, anxiety, depression, psychosis), male sex, older age, contemplation of violent methods, a humiliating social stressor, and drug use (including long-term sedative or alcohol use), which contributes to impulsiveness or mood swings. Successful treatment of the patient at risk for suicide cannot be achieved if the patient continues to abuse drugs.

The patient’s current mood status is best evaluated by direct evaluation of plans and concerns about the future, personal reactions to the attempt, and thoughts about the reactions of others. Measurement of mood is often facilitated by using a standardized instrument such as the Hamilton or Montgomery-Asberg clinician-administered rating scales or the self-administered Patient Health Questionnaire-9. Such measures allow for initial assessment as well as ongoing treatment tracking. The patient’s immediate resources should also be assessed—people who can be significantly involved (most important), family support, job situation, financial resources, etc. Suicide risk can be specifically assessed using an instrument such as the Columbia-Suicide Severity Risk Scale.

If hospitalization is not indicated (eg, gestures, impulsive attempts; see above), the clinician must formulate and institute a treatment plan or make an adequate referral. (The National Suicide Prevention Lifeline, 1-800-273-8255, may be of assistance.) Medication should be dispensed in small amounts to at-risk patients. Although TCAs and SSRIs are associated with an equal incidence of suicide attempts, the risk of successful suicide is higher with TCA overdose. Guns and medications should be removed from the patient’s household. Driving should be interdicted until the patient improves. The problem is often worsened by the long-term complications of the suicide attempt, eg, brain damage due to hypoxia, peripheral neuropathies caused by staying for long periods in one position causing nerve compressions, and medical or surgical problems such as esophageal strictures and tendon dysfunctions.

The reasons for self-mutilation, most commonly wrist cutting (but also autoamputation, autoamputation, and autoenucleation, which are associated with psychoses), may be very different from the reasons for a suicide attempt. The initial treatment plan, however, should presume suicidal ideation, and conservative treatment should be initiated.

Sleep disturbances in the depressions are discussed below.

### Treatment of Depression

#### A. Medical

Depression associated with reactive disorders usually does not call for drug therapy and can be managed by psychotherapy and the passage of time. In severe cases—particularly when vegetative signs are significant and symptoms have persisted for more than a few weeks—antidepressant drug therapy is often effective. Drug therapy is also suggested by a family history of major depression in first-degree relatives or a past history of prior episodes.

The antidepressant medications may be conveniently classified into three groups: (1) the newer antidepressants, including the SSRIs and bupropion, duloxetine, venlafaxine, nefazodone, vilazodone, and mirtazapine, (2) the TCAs and clinically similar medications, and (3) the MAO inhibitors (see Table 25–8). These groups are described in greater detail below. ECT is effective in all types of depression and will also rapidly resolve a manic episode. It is also very effective for postpartum depression. Megavitamin treatment, acupuncture, and electrosleep are of unproved usefulness for any psychiatric condition. Repetitive transcranial magnetic stimulation has been approved by the FDA for individuals who have not responded to one trial of an antidepressant and is being evaluated for wider application but is still not covered by most insurers as a first-line treatment.

Hospitalization is necessary if suicide is a major consideration or if complex treatment modalities are required.

Medication selection is influenced by the history of previous responses if that information is available. If a relative has responded to a particular drug, this suggests that the patient may respond similarly. If no background information is available, a drug such as sertraline, 25 mg orally daily and increasing gradually up to 200 mg, or desipramine, starting with 50 mg orally and gradually increasing to 150 mg, can be selected and a full trial instituted. The medication trial should be monitored for worsening mood or suicidal ideation with patient assessments every 1–2 weeks until week 6. If successful, the medication should be continued for 6–12 months at the full therapeutic dose before tapering is considered. Antidepressants should usually be continued indefinitely at full dosage in individuals with a first episode of depression before the age of 20 or after the age of 50, with more than two episodes after age 40, at least one episode after age 50, or with three or more total episodes. The STAR*D trial suggests that if the response to the first medication is inadequate, the best alternatives are to switch to a second agent that may be from the same or different class of antidepressant; another option is to try augmenting the first agent with lithium (eg, 600–900 mg/d orally), bupropine (eg, 30–60 mg/d orally), or thyroid medication (eg, liothyronine, 25–50 mcg/d orally). The latter course is often taken when there has been at least a partial response to the initial drug. Dysthymia is also treated in this way. The Agency for Health Care Policy and Research has produced clinical practice guidelines that outline one algorithm of treatment decisions (Figure 25–2).

Psychotic depression should be treated with a combination of an antipsychotic such as olanzapine and an
Stimulants such as dextroamphetamine (5–30 mg/d orally) and methylphenidate (10–45 mg/d orally) have enjoyed a resurgence of interest for the short-term treatment of depression in medically ill and geriatric patients. Their 50–60% efficacy rate is slightly below that of other agents. The stimulants are notable for rapid onset of action compared to antidepressant such as an SSRI at their usual doses. Mifepristone may have specific and early activity against psychotic depression.

Major depression with atypical features or seasonal onset can be treated with an MAO inhibitor or an SSRI with good results.

Stimulants such as dextroamphetamine (5–30 mg/d orally) and methylphenidate (10–45 mg/d orally) have enjoyed a resurgence of interest for the short-term treatment of depression in medically ill and geriatric patients. Their 50–60% efficacy rate is slightly below that of other agents. The stimulants are notable for rapid onset of action compared to antidepressant such as an SSRI at their usual doses. Mifepristone may have specific and early activity against psychotic depression.

Major depression with atypical features or seasonal onset can be treated with an MAO inhibitor or an SSRI with good results.

Figure 25–2. Overview of treatment for depression. (Reproduced from Agency for Health Care Policy and Research: Depression in Primary Care. Vol. 2: Treatment of Major Depression. United States Department of Health and Human Services, 1993.)
and mirtazapine, which selectively blocks presynaptic serotonin and is a partial agonist at the 5HT1A receptors; vilazodone, which inhibits the reuptake of serotonin but also inhibits the 5-HT2 postsynaptic receptors; nefazodone, which blocks the 5-HT2 receptors and enhances both noradrenergic and serotonergic transmission. All of these antidepressants are effective in the treatment of depression, both typical and atypical. The SSRI medications have been effective in the treatment of panic attacks, bulimia, generalized anxiety disorder, OCD, and PTSD. They do not seem to be as clearly effective in some pain syndromes as the TCAs, although venlafaxine may have some efficacy in the treatment of neuropathic pain, and duloxetine is FDA-approved for the treatment of diabetic peripheral neuropathy and fibromyalgia.

Most of the medications in this group tend to be activating and are given in the morning so as not to interfere with sleep. Some patients, however, may have sedation, requiring that the drug be given at bedtime. This reaction occurs most commonly with paroxetine, fluvoxamine, and mirtazapine. The SSRIs can be given in once-daily dosage. Nefazodone and venlafaxine are usually given twice daily. Bupropion and venlafaxine are available in extended-release formulations and can be given once daily. There is usually some delay in response; fluoxetine, for example, requires 2–6 weeks to act in depression, 4–8 weeks to be effective in panic disorder, and 6–12 weeks in treatment of OCD. The starting dose (10 mg) is given for 1 week before increasing to the average daily oral dose of 20 mg for depression, while OCD may require up to 80 mg daily. Some patients, particularly the elderly, may tolerate and benefit from as little as 10 mg/d or every other day. The other SSRIs have shorter half-lives and a lesser effect on hepatic enzymes, which reduces their impact on the metabolism of other medications (thus not increasing significantly the serum concentrations of other medications as much as fluoxetine). The shorter half-lives also allow for more rapid clearing if adverse side effects appear. Venlafaxine appears to be more effective with doses > 200 mg/d orally, although some individuals respond to doses as low as 75 mg/d.

The side effects common to all of these medications are headache, nausea, tinnitus, insomnia, and nervousness. Akathisia has been common with the SSRIs; other extrapyramidal symptoms (eg, dystonias) have occurred infrequently but particularly in withdrawal states. Because SSRIs affect platelet serotonin levels, abnormal bleeding can occur. Sertraline and citalopram appear to be the safest agents in this class when used with warfarin. Sexual side effects of erectile dysfunction, retrograde ejaculation, and dysorgasmia are very common with the SSRIs. Oral phosphodiesterase-5 inhibitors (such as sildenafil, 25–50 mg; tadalafil, 5–20 mg; or vardenafil, 10–20 mg taken 1 hour prior to sexual activity) can improve erectile dysfunction in some patients. Adjunctive bupropion (75–150 mg orally daily) may also help with restoring erectile function. Cyproheptadine, 4 mg orally prior to sexual activity, may be helpful in countering drug-induced anorgasmia. The SSRIs are strong serotonin uptake blockers and may in high doses or in combination with MAO inhibitors, including the antiparkinsonian drug selegiline, cause a “serotonin syndrome.” This syndrome is manifested by rigidity, hyperthermia, autonomic instability, myoclonus, confusion, delirium, and coma. This syndrome can be a particularly troublesome problem in the elderly. Several cases of angina have been reported in association with SSRIs. However, current research indicates that SSRIs are safer agents to use than TCAs in patients with cardiac disease. A study has found that sertraline is a safe and effective antidepressant treatment in patients with acute myocardial infarction or unstable angina.

Withdrawal syndromes have been reported for the SSRIs and venlafaxine. These include dysphoric mood, agitation, and a flu-like state. These medications should be discontinued gradually over a period of weeks or months to reduce the risk of withdrawal phenomena. Fluoxetine, fluvoxamine, sertraline, venlafaxine, and citalopram in customary antidepressant doses may increase the risk of major fetal malformation when used during pregnancy; however, the absolute risk of congenital defects is considered low. Paroxetine may be associated with a twofold increased risk of cardiac abnormalities. Postpartum developmental effects of antidepressants have been thought
to be minimal, however, this question calls for ongoing investigation. A 2010 study of depressed women in their third trimester of pregnancy, comparing those who were treated with an SSRI versus those who were untreated, suggests the SSRI may have relatively delayed gross motor development at 6 months. Peripartum effects may be a concern and are documented anecdotally in the literature. At the same time, maternal major mood disorder in pregnancy by itself carries its own risks to the mother and fetus and has been linked to low birth weight and preterm delivery. Postpartum effects of prenatal depression have not been studied. The decision to use SSRIs and other psychotropic agents during pregnancy and postpartum must be a collaborative decision based on a thorough risk-benefit analysis for each individual.

Venlafaxine is reported to be well-tolerated without significant anticholinergic or cardiovascular side effects. Nausea, nervousness, and profuse sweating appear to be the major side effects. Venlafaxine appears to have few drug-drug interactions. It does require monitoring of blood pressure because dose-related hypertension may develop in some individuals. Desvenlafaxine, a newer form of the drug, is started at its target dose of 50 mg/d orally and does not require upward titration. Duloxetine may also result in small increases in blood pressure. Common side effects include dry mouth, dizziness, and fatigue. Inhibitors of 1A2 and 2D6 may increase duloxetine levels with a risk of toxicity.

Nefazodone appears to lack the anticholinergic effects of the TCAs and the agitation sometimes induced by SSRIs. Nefazodone should not be given with terfenadine, astemizole, or cisapride. (Terfenadine, astemizole, and cisapride are not commercially available in the United States.) Because nefazodone inhibits the liver’s cytochrome P450 3A4 isoenzymes, concurrent use of these medications can lead to serious QT prolongation, ventricular tachycardia, or death. Through the same mechanism of enzyme inhibition, nefazodone can elevate cyclosporine levels sixfold to tenfold. Nefazodone has been given an FDA warning because it has been implicated in liver failure in rare cases. Pretreatment and ongoing monitoring of liver enzymes are indicated.

Mirtazapine is thought to enhance central noradrenergic and serotonergic activity with minimal sexual side effects compared with the SSRIs. Its action as a potent antagonist of histaminergic receptors may make it a useful agent for patients with depression and insomnia. It is also an effective antiepileptic due to its antagonism of the 5-HT3 receptor. Its most common adverse side effects include somnolence, increased appetite, weight gain, lipid abnormalities, and dizziness. There have been reports of agranulocytosis in 2 of 2796 patients. Although it is metabolized by P450 isoenzymes, it is not an inhibitor of this system. It is given in a single oral dose at bedtime starting at 15 mg and increasing in 15-mg increments every week or every other week up to 45 mg.

2. Tricyclic antidepressants (TCAs) and clinically similar medications—TCAs were the mainstay of drug therapy for depression for many years. They have also been effective in panic disorders, pain syndromes, and anxiety states. Specific ones have been effective in OCD (clomipramine), enuresis (imipramine), psychotic depression (amoxapine), and reduction of craving in cocaine withdrawal (desipramine).

TCAs are characterized more by their similarities than by their differences. There is a lag in clinical response for up to several weeks, largely the result of anticholinergic side effects that prevent rapid increase in dosage. They tend to affect both serotonin and norepinephrine reuptake; some medications act mainly on the former and others principally on the latter neurotransmitter system. Individuals receiving the same dosages vary markedly in therapeutic drug levels achieved (elderly patients require smaller doses), and determination of plasma drug levels is helpful when clinical response has been disappointing. Nortriptyline is usually effective when plasma levels are between 50 and 150 ng/mL; imipramine at plasma levels of 200–250 ng/mL; and desipramine at plasma levels of 100–250 ng/mL. High blood levels are not more effective than moderate levels and may be counterproductive (eg, delirium, seizures). Patients with gastrointestinal side effects benefit from plasma level monitoring to assess absorption of the drug. Most TCAs can be given in a single dose at bedtime, starting at fairly low doses (eg, nortriptyline 25 mg orally) and increasing by 25 mg every several days as tolerated until the therapeutic response is achieved (eg, nortriptyline, 100–150 mg) or to maximum dose if necessary (eg, nortriptyline, 150 mg). The most common cause of treatment failure is an inadequate trial. A full trial consists of giving maximum daily dosage for at least 6 weeks. Because of marked anticholinergic and sedating side effects, clomipramine is started at a low dose (25 mg/d orally) and increased slowly in divided doses up to 100 mg/d, held at that level for several days, and then gradually increased as necessary up to 250 mg/d. Any of the TCA-like medications should be started at very low doses (eg, 10–25 mg/d) and increased slowly in the treatment of panic disorder.

The TCAs have anticholinergic side effects to varying degrees (amitriptyline 100 mg is equivalent to atropine 5 mg). One must be particularly wary of the effect in elderly men with prostatic hyperplasia. The anticholinergic effects also predispose to other medical problems such as constipation, heat stroke, or dental problems from xerostomia. Orthostatic hypotension is fairly common, is not dose-dependent and may not remit with time on medication; this may predispose to falls and hip fractures in the elderly. Cardiac effects of the TCAs are functions of the anticholinergic effect, direct myocardial depression (quinidine-like effect), and interference with adrenergic neurons. These factors may produce altered rate, rhythm, and contractility, particularly in patients with preexisting cardiac disease, such as bundle-branch or bifascicular block. Electrocardiographic changes range from benign ST segment and T wave changes and sinus tachycardia to a variety of complex and serious arrhythmias, the latter requiring a change in medication. Because TCAs have class I antiarrhythmic effects, they should be used with caution in patients with ischemic heart disease, arrhythmias, or conduction disturbances. SSRIs or the atypical antidepressants are better initial choices for this population. TCAs lower
the seizure threshold so this is of particular concern in patients with a propensity for seizures (eg, previous head injury, alcohol withdrawal). Loss of libido and erectile, ejaculatory, and orgasmic dysfunction are fairly common and can compromise compliance. Trazodone rarely causes priapism (1 in 9000), but when it occurs, it requires treatment within 12 hours (epinephrine 1:1000 injected into the corpus cavernosum). Delirium, agitation, and mania are infrequent complications of the TCAs but can occur. Sudden discontinuation of some of these medications can produce “cholinergic rebound,” manifested by headaches and nausea with abdominal cramps. Overdoses of TCAs are often serious because of the narrow therapeutic index and quinidine-like effects (see Chapter 38).

3. Monoamine oxidase inhibitors—The MAO inhibitors are generally used as third-line medications for depression (after a failure of SSRIs, TCAs, or the atypical antidepressants) because of the dietary and other restrictions required (see below and Table 25–7). They should be considered third-line medications for refractory panic disorder as well as depression; however, this hierarchy has become more flexible since MAO inhibitor skin patches (selegiline) have become available. They deliver the MAO inhibitor to the bloodstream bypassing the gastrointestinal tract so that dietary restrictions are not necessary in the lowest dosage strength (6 mg/24 h).

Oral MAO inhibitors are administered in gradual stepwise dosage and may be given in the morning or evening, depending upon their effect on sleep. They tend to take effect in a fairly low dosage range (Table 25–8). Blood levels are not congruent with therapeutic response.

The MAO inhibitors commonly cause symptoms of orthostatic hypotension (which may persist) and sympathomimetic effects of tachycardia, sweating, and tremor. Nausea, insomnia (often associated with intense afternoon drowsiness), and sexual dysfunction are common. Trazodone, 25–75 mg orally at bedtime, may ameliorate the MAO-induced insomnia. Central nervous system effects include agitation and toxic psychoses. Dietary limitations (see Table 25–7) and abstinence from drug products containing phenylpropanolamine, phenylephrine, meperidine, dextromethorphan, and pseudoephedrine are mandatory for MAO-A type inhibitors (those marketed for treatment of depression), since the reduction of available MAO leaves the patient vulnerable to exogenous amines (eg, tyramine in foodstuffs).

Treatment for a resultant hypertensive crisis has been the same as for pheochromocytoma (see Chapter 26), but there have been reports of success with nifedipine, 10 mg chewed and placed under the tongue, normalizing blood pressure in 1–5 minutes. The restrictions on the proscribed foodstuffs and sympathomimetic medications are in effect during treatment and for 2–3 weeks after cessation of therapy. Termination of therapy with MAO inhibitors may be associated with anxiety, agitation, cognitive slowing, and headache. Very gradual withdrawal and short-term benzodiazepine therapy will ameliorate symptoms.

4. Switching and combination therapy—If the therapeutic response has been poor after an adequate trial with the chosen drug, the diagnosis should be reassessed. Assuming that the trial has been adequate and the diagnosis is correct, a trial with a second drug is appropriate. In switching from one group to another, an adequate “washout time” must be allowed. This is critical in certain situations—eg, in switching from an MAO inhibitor to a TCA, allow 2–3 weeks between stopping one drug and starting another; in switching from an SSRI to an MAO inhibitor, allow 4–5 weeks. In switching within groups—eg, from one TCA to another (amitriptyline to desipramine, etc)—no washout time is needed, and one can rapidly decrease the dosage of one drug while increasing the other. In clinical practice, adjunctive treatment with lithium, buspirone, or thyroid hormone may be helpful in depression. The adjunctive use of low-dose atypical antipsychotics such as aripiprazole, olanzapine, and risperidone in the treatment of patients with refractory depression is supported by research. The side effect risk is the same as when treating psychosis. The FDA has approved aripiprazole for this purpose. Adding an atypical agent requires monitoring body mass index, lipids, and glucose. Combining two antidepressants, or adding an antipsychotic to an antidepressant, requires caution and is usually reserved for clinicians who feel comfortable managing this or after psychiatric consultation.

5. Maintenance and tapering—When clinical relief of symptoms is obtained, medication is continued for 12 months in the effective maintenance dosage, which is the dosage required in the acute stage. The full dosage should be continued indefinitely when the individual has a first episode before age 20 or after age 50, is over age 40 with two episodes, at least one episode after age 50, or has had three episodes at any age. Major depression should often be considered a chronic disease. If the medication is being tapered, it should be done gradually over several months, monitoring closely for relapse.

6. Drug interactions—Interactions with other medications are listed in Table 25–9.

7. Electroconvulsive therapy—ECT causes a generalized central nervous system seizure (peripheral convulsion is not necessary) by means of electric current. The key objective is to exceed the seizure threshold, which can be accomplished by a variety of means. The mechanism of action is not known, but it is thought to involve major neurotransmitter responses at the cell membrane. Electrical current insufficient to cause a seizure produces no therapeutic benefit.

ECT is the most effective (about 70–85%) treatment of severe depression—particularly the delusions and agitation

**Note:** Terfenadine, astemizole, and cisapride are not commercially available in the United States. MAOIs, monoamine oxidase inhibitors.

Commonly seen with depression in the elderly, it is indicated when medical conditions preclude the use of antidepressants, nonresponsiveness to these medications, and extreme suicidality. Comparative controlled studies of ECT in severe depression show that it is more effective than pharmacotherapy. It is also effective in the manic disorders and psychoses during pregnancy (when medications may be contraindicated). It has not been shown to be helpful in chronic schizophrenic disorders, and it is generally not used in acute schizophrenic episodes unless medications are not effective and it is urgent that the psychosis be controlled (eg, a catatonic stupor complicating an acute medical condition).

The most common side effects are memory disturbance and headache. Memory loss or confusion is usually related to the number and frequency of ECT treatments and proper oxygenation during treatment. Unilateral ECT is associated with less memory loss than bilateral ECT. Some memory loss is occasionally permanent, but most memory faculties return to full capacity within several weeks. There have been reports that lithium administration concurrent with ECT resulted in greater memory loss.

Increased intracranial pressure is a serious contraindication. Other problems such as cardiac disorders, aortic aneurysms, bronchopulmonary disease, and venous thrombosis are relative contraindications and must be evaluated in light of the severity of the medical problem versus the need for ECT. Serious complications arising from ECT occur in < 1 in 1000 cases. Most of these problems are cardiovascular or respiratory in nature (eg, aspiration of gastric contents). Poor patient understanding and lack of acceptance of the technique by the public are the biggest obstacles to the use of ECT.

### 8. Phototherapy

Phototherapy is used in major depression with seasonal onset. It consists of exposure (at a 3-foot distance) to a light source of 2500 lux for 2 hours daily. Light visors are an adaptation that provides greater mobility and an adjustable light intensity. The dosage varies, with some patients requiring morning and night exposure. One effect is alteration of biorhythm through photoperiods, melatonin mechanisms.

### 9. Experimental treatments

In preliminary studies, transcranial magnetic stimulation appears to be effective in nonpsychotic depression. Its use in this condition has been approved by the FDA for individuals who have not responded to an antidepressant. It is usually delivered in a course of 16–20 sessions over 1 month. Vagal nerve stimulation has shown some promise in extremely refractory cases and is approved by the FDA but has not been approved by many insurers.

### B. Psychological

It is seldom possible to engage an individual in penetrating psychotherapeutic endeavors during the acute stage of a severe depression. While medications may be taking effect, a supportive approach to strengthen existing coping mechanisms and appropriate consideration of the patient’s continuing need to function at work, to engage in recreational activities, etc, are necessary as the severity of the...
depression lessens. If the patient is not seriously depressed, it is often quite appropriate to initiate intensive psychotherapeutic efforts, since flux periods are a good time to effect change. A catharsis of repressed anger and guilt may be beneficial. Therapy during or just after the acute stage may focus on coping techniques, with some practice of alternative choices. Depression-specific psychotherapies help improve self-esteem, increase assertiveness, and lessen dependency. Interpersonal psychotherapy for depression has shown efficacy in the treatment of acute depression, helping patients master interpersonal stresses and develop new coping strategies. Cognitive behavioral therapy for depression addresses patients’ patterns of negative thoughts, called cognitive distortions, that lead to feelings of depression and anxiety. Treatment usually includes homework assignments such as keeping a journal of cognitive distortions and of positive responses to them. The combination of drug therapy plus interpersonal psychotherapy or cognitive behavioral therapy is more effective than either modality alone. It is usually helpful to involve the spouse or other significant family members early in treatment. Mindfulness-based cognitive therapy has reduced relapse rates in several randomized controlled trials. In two studies, it was as effective as maintenance medication in preventing relapse. This therapy incorporates meditation and teaches patients to distance themselves from depressive thinking. It may be a preferable alternative for individuals who wish to have an alternative to long-term medications to stay free of depressive episodes.

C. Social

Flexible use of appropriate social services can be of major importance in the treatment of depression. Since alcohol is often associated with depression, early involvement in alcohol treatment programs such as Alcoholics Anonymous can be important to future success (see Alcohol Dependency and Abuse, below). The structuring of daily activities during severe depression is often quite difficult for the patient, and loneliness is often a major factor. The help of family, employer, or friends is often necessary to mobilize the patient who experiences no joy in daily activities and tends to remain uninvolved and to deteriorate. Insistence on sharing activities will help involve the patient in simple but important daily functions. In some severe cases, the use of day treatment centers or support groups of a specific type (eg, mastectomy groups) is indicated. It is not unusual for a patient to have multiple legal, financial, and vocational problems requiring legal and vocational assistance.

D. Behavioral

When depression is a function of self-defeating coping techniques such as passivity, the role-playing approach can be useful. Behavioral techniques, including desensitization, may be used in problems such as phobias where depression is a by-product. When depression is a regularly used interpersonal style, behavioral counseling to family members or others can help in extinguishing the behavior in the patient. Behavioral activation, a technique of motivating depressed patients to begin engaging in pleasurable activities, has been shown to be a useful depression-specific psychotherapy.

Treatment of Mania

Acute manic or hypomanic symptoms will respond to lithium or valproic acid after several days of treatment, but it is increasingly common to use atypical neuroleptics as adjunctive treatment or monotherapy. High-potency benzodiazepines (eg, clonazepam) may also be useful adjuncts in managing acute cases. Some schizoaffective disorders and some cases of so-called schizophrenia are probably atypical bipolar affective disorder, for which lithium treatment may be effective.

A. Neuroleptics

Acute manic symptoms of agitation and psychosis may be treated initially with the atypical antipsychotic olanzapine, (eg, 5–20 mg orally), risperidone (2–3 mg orally), or aripiprazole (15–30 mg) in conjunction with a benzodiazepine if indicated. Alternatively, when behavioral control is immediately necessary, olanzapine in an injectable form (2.5–10 mg intramuscularly) or haloperidol, 5–10 mg orally or intramuscularly repeated as needed until symptoms subside, may be used. The dosage of the neuroleptic may be gradually reduced after lithium or another mood stabilizer is started (see below). Olanzapine is approved as a maintenance treatment for bipolar disorder.

B. Clonazepam

Clonazepam can be an alternative or adjunct to a neuroleptic in controlling acute behavioral symptoms. Clonazepam has the advantage of causing no extrapyramidal side effects. Although 1–2 mg orally every 4–6 hours may be effective, up to 16 mg/d may be necessary.

C. Lithium

As a prophylactic drug for bipolar affective disorder, lithium significantly decreases the frequency and severity of both manic and depressive attacks in about 70% of patients. A positive response is more predictable if the patient has a low frequency of episodes (no more than two per year with intervals free of psychopathology). A positive response occurs more frequently in individuals who have blood relatives with a diagnosis of manic or hypomanic attacks. Patients who swing rapidly back and forth between manic and depressive attacks (at least four cycles per year) usually respond poorly to lithium prophylaxis initially, but some improve with continued long-term treatment. Carbamazepine (see below) has been used with success in this group.

In addition to its use in manic states, lithium is sometimes useful in the prophylaxis of recurrent unipolar depressions (perhaps undiagnosed bipolar disorder). Lithium may ameliorate nonspecific aggressive behaviors and dyscontrol syndromes. The dosages are the same as used in bipolar disorder. Most patients with bipolar disease can be managed long-term with lithium alone, although some will require continued or intermittent use of a neuroleptic, antidepressant, or carbamazepine. An excellent resource for information is the Lithium Information Center, Madison Institute of Medicine, 7617

Before treatment, the clinical workup should include a medical history and physical examination; complete blood count; T4, thyroid-stimulating hormone, blood urea nitrogen (BUN), serum creatinine, and serum electrolyte determinations; urinalysis; and electrocardiography (in patients over age 45 or with a history of cardiac disease).

1. Dosage—The common starting dosage of lithium carbonate is 300 mg orally two or three times daily, with trough blood levels measured after 5 days of treatment. In a small minority of patients, a slow release form or units of different dosage may be required. Lithium citrate is available as a syrup. The dosage is that required to maintain blood levels in the therapeutic range. For acute attacks, this ranges from 1 to 1.5 mEq/L. Although there is controversy about the optimal long-term maintenance dose, many clinicians reduce the acute level to 0.6–1 mEq/L in order to reduce side effects. The dose required to meet this need will vary in different individuals. For acute mania, doses of 1200–1800 mg/d are generally recommended. Augmentation of antidepressants is usually achieved with half of these doses. Once-a-day dosage is acceptable, but most patients have less nausea when they take the drug in divided doses with meals.

Lithium is readily absorbed, with peak serum levels occurring within 1–3 hours and complete absorption in 8 hours. Half of the total body lithium is excreted in 18–24 hours (95% in the urine). Blood for lithium levels should be drawn 12 hours after the last dose. Serum levels should be measured 5–7 days after initiation of treatment and changes in dose. For maintenance treatment, lithium levels should be monitored initially every 1–2 months but may be measured every 6–12 months in stable, long-term patients. Levels should be monitored more closely when there is any condition that causes volume depletion (eg, diarrhea, dehydration, use of diuretics).

2. Side effects—Mild gastrointestinal symptoms (take lithium with food and in divided doses), fine tremors (treat with propranolol, 20–60 mg/d orally, only if persistent), slight muscle weakness, and some degree of somnolence are early side effects that are usually transient. Moderate polyuria (reduced renal responsiveness to ADH) and polydipsia (associated with increased plasma renin concentration) are often present. Potassium administration can blunt this effect, as may once-daily dosing of lithium. Weight gain (often a result of calories in fluids taken for polydipsia) and leukocytosis not due to infection are fairly common.

Other side effects include goiter (3%; often euthyroid), hypothyroidism (10%; concomitant administration of lithium and iodide or lithium and carbamazepine enhances the hypothyroid and goitrogenic effect of either drug), changes in the glucose tolerance test toward a diabetes-like curve, nephrogenic diabetes insipidus (usually resolving about 8 weeks after cessation of lithium therapy), nephrotic syndrome, edema, folate deficiency, and pseudotumor cerebri (ophthalmoscopy is indicated if there are complaints of headache or blurred vision). A metallic taste, hair loss, and Raynaud phenomenon have been reported in a few cases. Thyroid and kidney function should be checked at 3- to 4-month intervals. Most of these side effects subside when lithium is discontinued; when residual side effects exist, they are usually not serious. Most clinicians treat lithium-induced hypothyroidism (more common in women) with thyroid hormone while continuing lithium therapy. Hypercalcemia and elevated parathyroid hormone levels occur in some patients. Electrocardiographic abnormalities (principally T wave flattening or inversion) may occur during lithium administration but are not of major clinical significance. Sinoatrial block may occur, particularly in the elderly. Other medications that prolong intraventricular conduction, such as TCAs, must be used cautiously in conjunction with lithium. Lithium impairs ventilatory function in patients with airway obstruction. Lithium alone does not have a significant effect on sexual function, but when combined with benzodiazepines (clonazepam in most symptomatic patients) it causes sexual dysfunction in about 50% of men. Lithium may precipitate or exacerbate psoriasis in some patients.

Patients receiving long-term lithium therapy may have cogwheel rigidity and, occasionally, other extrapyramidal signs. Lithium potentiates the parkinsonian effects of haloperidol. Long-term lithium therapy has also been associated with a relative lowering of the level of memory and perceptual processing (affecting compliance in some cases). Some impairment of attention and emotional reactivity has also been noted. Lithium-induced delirium with therapeutic lithium levels is an infrequent complication usually occurring in the elderly and may persist for several days after serum levels have become negligible. Encephalopathy has occurred in patients receiving combined lithium and neuroleptic therapy and in those who have cerebrovascular disease, thus requiring careful evaluation of patients who develop neurotoxic signs at subtoxic blood levels.

Some reports have suggested that the long-term use of lithium may have adverse effects on kidney function (with interstitial fibrosis, tubular atrophy, or nephrogenic diabetest-insipidus). Persistent polyuria should require an investigation of the kidney’s ability to concentrate urine. A rise in serum creatinine levels is an indication for in-depth evaluation of kidney function and consideration of alternative treatments if the individual can tolerate a change. Incontinence has been reported in women, apparently related to changes in bladder cholinergic-adrenergic balance.

Prospective studies suggest that the overall risk imposed by lithium in pregnancy may be overemphasized. However, lithium exposure in early pregnancy does increase the frequency of congenital anomalies, especially Ebstein and other major cardiovascular anomalies. For women who take psychotropic medications who become pregnant, the decision to make a change in medication is complex and requires informed consent regarding the relative risks to the patient and fetus. Indeed, the risk of untreated bipolar disorder carries its own risks for pregnancy. Formula feeding should be considered in mothers taking lithium, since concentration in breast milk is one-third to half that in serum.
Frank toxicity usually occurs at blood lithium levels > 2 mEq/L. Because sodium and lithium are reabsorbed at the same loci in the proximal renal tubules, any sodium loss (diarrhea, use of diuretics, or excessive perspiration) results in increased lithium levels. Symptoms and signs include vomiting and diarrhea, the latter exacerbating the problem since more sodium is lost and more lithium is absorbed. Other symptoms and signs, some of which may not be reversible, include tremors, marked muscle weakness, confusion, dysarthria, vertigo, choreoathetosis, ataxia, hyperreflexia, rigidity, lack of coordination, myoclonus, seizures, opisthotonos, and coma. Toxicity is more severe in the elderly, who should be maintained on slightly lower serum levels. Lithium overdosage may be accidental or intentional or may occur as a result of poor monitoring.

Patients with massive ingestions of lithium or blood lithium levels > 2.5 mEq/L should be treated with induced emesis and gastric lavage. If kidney function is normal, osmotic and saline diuresis increases renal lithium clearance. Urinary alkalinization is also helpful, since sodium bicarbonate decreases lithium reabsorption in the proximal tubule, as does acetazolamide. Aminophylline potentiates the diuretic effect by increasing the clearance of lithium. Medications affecting the distal loop have no effect on lithium excretion. If kidney function is normal, reducing lithium intake to achieve therapeutic lithium levels. Concurrent use of lithium and angiotensin-converting enzyme inhibitors requires a 50–75% reduction in lithium levels. Loop diuretics (furosemide, ethacrynic acid, bumetanide) do not appear to alter serum lithium levels. Monitoring of lithium levels. Loop diuretics (furosemide, ethacrynic acid, bumetanide) do not appear to alter serum lithium levels.

Compliance with lithium therapy is adversely affected by the loss of some hypomanic experiences valued by the patient. These include social extroversion and a sense of heightened enjoyment in many activities such as sex and business dealings, often with increased productivity in the latter.

### 3. Drug interactions

Patients receiving lithium should use diuretics with caution and only under close medical supervision. The thiazide diuretics cause increased lithium reabsorption from the proximal renal tubules, resulting in increased serum lithium levels (Table 25–10), and adjustment of lithium intake must be made to compensate for this. Reduce lithium dosage by 25–40% when the patient is receiving 50 mg of hydrochlorothiazide daily. Potassium-sparing diuretics (spironolactone, amiloride, triamterene) may also increase serum lithium levels and require careful monitoring of lithium levels. Loop diuretics (furosemide, ethacryninc acid, bumetanide) do not appear to alter serum lithium levels. Concurrent use of lithium and angiotensin-converting enzyme inhibitors requires a 50–75% reduction in lithium intake to achieve therapeutic lithium levels.

### D. Valproic Acid

Valproic acid (divalproex) is an antiseizure drug whose activity is at least partially related to GABA neurotransmission. It is a first-line treatment for mania because it has a broader index of safety than lithium. This issue is particularly important in AIDS or other medically ill patients prone to dehydration or malabsorption with wide swings in serum lithium levels. Valproic acid has also been used effectively in panic disorder and migraine headache. Treatment is often started at a dose of 750 mg/d orally in divided doses, and dosage is then titrated to achieve therapeutic serum levels. Oral loading in acutely manic bipolar patients in an inpatient setting (initiated at a dosage of 20 mg/kg/d) can safely achieve serum therapeutic levels in 2–3 days. Concomitant use of aspirin may increase valproate levels, carbamazepine or phenytoin may decrease valproate levels, while warfarin levels may be elevated by valproate. Gastrointestinal symptoms and weight gain are the main side effects. Liver function tests, complete blood counts, glucose levels, and weight should be monitored at 2 weeks, 4 weeks, and at 3 months initially and annually or more frequently thereafter based on clinical judgment. Significant teratogenic effects are a concern so pregnancy should be ruled out prior to initiation.

### E. Carbamazepine

Carbamazepine, an antiseizure drug that stabilizes the activity of cell membranes, has been used with increasing frequency in the treatment of bipolar patients who cannot be satisfactorily treated with lithium (nonresponsive, excessive side effects, or rapid cycling). It is often effective at 800–1600 mg/d orally. It has also been used in the treatment of resistant depressions, alcohol withdrawal, and hallucinations (in conjunction with neuroleptics) and in patients with behavioral dyscontrol or panic attacks. It suppresses some phases of kindling (see Stimulants) and has been used to treat residual symptoms in previous stimulant abusers (eg, PTSD with impulse control problems). Dose-related side effects include sedation and ataxia. Dosages

ACE, angiotensin-converting enzyme; COX-2, cyclooxygenase-2.
start at 400–600 mg orally daily and are increased slowly to therapeutic levels. Skin rashes and a mild reduction to white count are common. SIADH occurs rarely. Non-steroidal anti-inflammatory medications (except aspirin), the antibiotics erythromycin and isoniazid, the calcium channel blockers verapamil and diltiazem (but not nifedipine), fluoxetine, propoxyphene, and cimetidine all increase carbamazepine levels. Carbamazepine can be effective in conjunction with lithium, although there have been reports of reversible neurotoxicity with the combination. Carbamazepine stimulates hepatic microsomal enzymes and so tends to decrease levels of haloperidol and oral contraceptives. It also lowers T₄, free T₄, and T₃ levels. Cases of fetal malformation (particularly spina bifida) have been reported along with growth deficiency and developmental delay. Liver tests and complete blood counts should be monitored in patients taking carbamazepine. Genetic studies suggest that screening for the HLA-B1502 allele in the Han Chinese population and the HLA-A3101 allele in northern Europeans may help target individuals more susceptible to a serious rash. Oxcarbazepine, a derivative of carbamazepine, does not appear to induce its own metabolism and is associated with fewer drug interactions, although it may impose a higher risk of hyponatremia. FDA-approved for partial seizures, oxcarbazepine may have efficacy in acute mania. It appears to be a safer alternative to carbamazepine due to its lower risk of hepatotoxicity.

F. Lamotrigine

Lamotrigine is thought to inhibit neuronal sodium channels and the release of the excitatory amino acids, glutamate and aspartate. It is FDA approved for long-term maintenance of bipolar disorder. Two double-blind studies support its efficacy in the treatment of acute bipolar depression as adjunctive therapy or as monotherapy. Its metabolism is inhibited by coadministration of valproic acid—doubling its half-life—and accelerated by hepatic enzyme-inducing agents such as carbamazepine. More frequent mild side effects include headache, dizziness, nausea, and diplopia. Rash occurring in 10% of patients is an indication for immediate cessation of dosing, since lamotrigine has been associated with Stevens-Johnson syndrome (1:1000) and, rarely, toxic epidermal necrolysis. Dosing starts at 25–50 mg/d orally and is titrated upward slowly to decrease the likelihood of rash. Slower titration and a lower total dose are indicated for patients taking valproic acid.

Prognosis

Reactive depressions are usually time-limited, and the prognosis with treatment is good if a pathologic pattern of adjustment does not intervene. Major affective disorders frequently respond well to a full trial of drug treatment.

Mania and bipolar disorder have a good prognosis with adequate treatment, although patient adherence to treatment is often quite challenging.

Banerjee S et al. Sertraline or mirtazapine for depression in dementia (HTA-SADD); a randomised, multicentre, double-blind, placebo-controlled trial. Lancet. 2011 Jul 30;378(9789):403–11. [PMID: 21764118]

SLEEP DISORDERS

Sleep consists of two distinct states as shown by electroencephalographic studies: (1) REM (rapid eye movement) sleep, also called dream sleep, D state sleep, paradoxical sleep, and (2) NREM (non-REM) sleep, also called S stage sleep, which is divided into stages 1, 2, 3, and 4 and is recognizable by different electroencephalographic patterns. Stages 3 and 4 are “delta” sleep. Dreaming occurs mostly in REM and to a lesser extent in NREM sleep.

Sleep is a cyclic phenomenon, with four or five REM periods during the night accounting for about one-fourth of the total night’s sleep (1.5–2 hours). The first REM period occurs about 80–120 minutes after onset of sleep and lasts about 10 minutes. Later REM periods are longer (15–40 minutes) and occur mostly in the last several hours of sleep. Most stage 4 (deepest) sleep occurs in the first several hours.

Age-related changes in normal sleep include an unchanging percentage of REM sleep and a marked decrease in stage 3 and stage 4 sleep, with an increase in waking periods during the night. These normal changes, early bedtimes, and daytime naps play a role in the increased complaints of insomnia in older people. Variations in sleep patterns may be due to circumstances (eg, “jet lag”) or to idiosyncratic patterns (“night owls”) in persons who perhaps because of different “biologic rhythms” habitually go to bed late and sleep late in the morning. Creativity and rapidity of response to unfamiliar situations are impaired by loss of sleep. There are also rare individuals who have chronic difficulty in adapting to a 24-hour sleep-wake cycle (desynchronization sleep disorder), which can be resynchronized by altering exposure to light.

The three major sleep disorders are discussed below.

1. Dyssomnias (Insomnia)

Classification & Clinical Findings

Patients may complain of difficulty getting to sleep or staying asleep, intermittent wakefulness during the night, early
Transient episodes are usually of little significance. Stress, caffeine, physical discomfort, daytime napping, and early bedtimes are common factors.

Psychiatric disorders are often associated with persistent insomnia. **Depression** is usually associated with fragmented sleep, decreased total sleep time, earlier onset of REM sleep, a shift of REM activity to the first half of the night, and a loss of slow wave sleep—all of which are non-specific findings. In **manic disorders**, sleeplessness is a cardinal feature and an important early sign of impending mania in bipolar cases. Total sleep time is decreased, with shortened REM latency and increased REM activity. Sleep-related panic attacks occur in the transition from stage 2 to stage 3 sleep in some patients with a longer REM latency in the sleep pattern preceding the attacks.

**Abuse of alcohol** may cause or be secondary to the sleep disturbance. There is a tendency to use alcohol as a means of getting to sleep without realizing that it disrupts the normal sleep cycle. Acute alcohol intake produces a decreased sleep latency with reduced REM sleep during the first half of the night. REM sleep is increased in the second half of the night, with an increase in total amount of slow wave sleep (stages 3 and 4). Vivid dreams and frequent awakenings are common. Chronic alcohol abuse increases stage 1 and decreases REM sleep (most medications delay or block REM sleep), with symptoms persisting for many months after the individual has stopped drinking. Acute alcohol or other sedative withdrawal causes delayed onset of sleep and REM rebound with intermittent awakening during the night.

**Heavy smoking** (more than a pack a day) causes difficulty falling asleep—apparently independently of the often associated increase in coffee drinking. Excess intake near bedtime of caffeine, cocaine, and other stimulants (eg, over-the-counter cold remedies) causes decreased total sleep time—mostly NREM sleep—with some increased sleep latency.

**Sedative-hypnotics**—specifically, the benzodiazepines, which are the most commonly prescribed medications to promote sleep—tend to increase total sleep time, decrease sleep latency, and decrease nocturnal awakening, with variable effects on NREM sleep. Withdrawal causes just the opposite effects and results in continued use of the drug for the purpose of preventing withdrawal symptoms. Antidepressants decrease REM sleep (with marked rebound on withdrawal in the form of nightmares) and have varying effects on NREM sleep. The effect on REM sleep correlates with reports that REM sleep deprivation produces improvement in some depressions.

Persistent insomnias are also related to a wide variety of medical conditions, particularly delirium, pain, respiratory distress syndromes, uremia, asthma, thyroid disorders, and nocturia due to benign prostatic hyperplasia. Sleep apnea and restless leg movement are described below. Adequate analgesia and proper treatment of medical disorders will reduce symptoms and decrease the need for sedatives.

**Treatment**

In general, there are two broad classes of treatment for insomnia, and the two may be combined: psychological (cognitive-behavioral) and pharmacologic. In situations of acute distress, such as a grief reaction, pharmacologic measures may be most appropriate. With primary insomnia, however, initial efforts should be psychologically based. This is particularly true in the elderly to avoid the potential adverse reactions of medications. The elderly population is at risk for complaints of insomnia because sleep becomes lighter and more easily disrupted with aging. Medical disorders that become more common with age may also predispose to insomnia.

### A. Psychological

Psychological strategies should include educating the patient regarding good **sleep hygiene**: (1) Go to bed only when sleepy. (2) Use the bed and bedroom only for sleeping and sex. (3) If still awake after 20 minutes, leave the bedroom, pursue a restful activity (such as a bath or meditation), and only return when sleepy. (4) Get up at the same time every morning regardless of the amount of sleep during the night. (5) Discontinue caffeine and nicotine, at least in the evening if not completely. (6) Establish a daily exercise regimen. (7) Avoid alcohol as it may disrupt continuity of sleep. (8) Limit fluids in the evening. (9) Learn and practice relaxation techniques. (10) Establish a bedtime ritual and a routine time for going to sleep. A 2009 study suggests that cognitive behavioral therapy for insomnia was as effective as zolpidem with benefits sustained 1 year after treatment.

### B. Medical

When the above measures are insufficient, medications may be useful. Lorazepam (0.5 mg orally nightly), temazepam (7.5–15 mg orally nightly) and the nonbenzodiazepine hypnotics, zolpidem (5–10 mg orally nightly), and zaleplon (5–10 mg orally nightly), are often effective for the elderly population and can be given in larger doses—twice what is prescribed for the elderly—in younger patients. A nonbenzodiazepine hypnotic, eszopiclone (2–3 mg orally), is similar in action to zolpidem and zaleplon but dissimilar in that it is not restricted to short-term use. A lower dose of 1 mg is indicated in the elderly or those with hepatic impairment. It is important to note that short-acting agents like triazolam or zolpidem may lead to amnestic episodes if used on a daily ongoing basis. Longer-acting agents such as flurazepam (half-life of > 48 hours) may accumulate in the elderly and lead to cognitive slowing, ataxia, falls, and somnolence. In general, it is appropriate to use medications for short courses of 1–2 weeks. The medications described above have largely replaced barbiturates as hypnotic agents because of their greater safety in overdose and their lesser hepatic enzyme induction effects. Antihistamines such as diphenhydramine (25 mg orally nightly) or hydroxyzine (25 mg orally nightly) may also be useful for sleep, as they produce no pharmacologic dependency; their anticholinergic effects may, however, produce confusion or urinary symptoms in the elderly. Trazodone, an atypical antidepressant, is a non–habit-forming, effective sleep medication in lower than antidepressant doses (25–150 mg orally at bedtime). Priapism is a rare side effect...
E. Shift Work Sleep Disorder

Shift work sleep disorder occurs when there is excessive fatigue as a consequence of work occurring during the normal sleep period.

Treatment

Narcolepsy can be managed by daily administration of a stimulant such as dextroamphetamine sulfate, 10 mg orally in the morning, with increased dosage as necessary. Modafinil is a schedule IV medication FDA-approved for treating the excessive daytime fatigue of narcolepsy as well as for shift work sleep disorder. Usual dosing is 200 mg orally each morning. Its mechanism of action is unknown, yet it is thought to be less of an abuse risk than stimulants that are primarily dopaminergic. Common side effects include headache and anxiety; however, modafinil appears to be generally well tolerated. Modafinil may reduce the efficacy of cyclosporine, oral contraceptives, and other medications by inducing their hepatic metabolism.

Imipramine, 75–100 mg orally daily, has been effective in treatment of cataplexy but not narcolepsy.

Periodic limb movement disorder and REM sleep behavior disorder can be treated with clonazepam with variable results. There is no treatment for Kleine-Levin syndrome.

Treatment of sleep apnea is discussed in Chapter 9.

3. Parasomnias (Abnormal Behaviors during Sleep)

These disorders are fairly common in children and less so in adults.

Classification & Clinical Findings

A. Sleep Terror

Sleep terror (pavor nocturnus) is an abrupt, terrifying arousal from sleep, usually in preadolescent boys although it may occur in adults as well. It is distinct from sleep panic attacks. Symptoms are fear, sweating, tachycardia, and confusion for several minutes, with amnesia for the event.

B. Nightmares

Nightmares occur during REM sleep; sleep terrors in stage 3 or stage 4 sleep.

C. Sleepwalking

Sleepwalking (somnambulism) includes ambulation or other intricate behaviors while still asleep, with amnesia for the event. It affects mostly children aged 6–12 years, and episodes occur during stage 3 or stage 4 sleep in the first third of the night and in REM sleep in the later sleep hours. Sleepwalking in elderly people may be a feature of dementia. Idiosyncratic reactions to drugs (eg, marijuana, alcohol) and medical conditions (eg, partial complex seizures) may be causative factors in adults.

D. Enuresis

Enuresis is involuntary micturition during sleep in a person who usually has voluntary control. Like other parasomnias,
it is more common in children, usually in the 3–4 hours after bedtime, but is not limited to a specific stage of sleep. Confusion during the episode and amnesia for the event are common.

**Treatment**

Treatment for sleep terrors is with benzodiazepines (eg, diazepam, 5–20 mg orally at bedtime), since it will suppress stage 3 and stage 4 sleep. Somnambulism responds to the same treatment for the same reason, but simple safety measures should not be neglected. Enuresis may respond to imipramine, 50–100 mg orally at bedtime, although desmopressin nasal spray (an ADH preparation) has increasingly become the treatment of choice for nocturnal enuresis. Behavioral approaches (eg, bells that ring when the pad gets wet) have also been successful.

**DISORDERS OF AGGRESSION**

Aggression and violence are symptoms rather than diseases, and most frequently they are not associated with an underlying medical condition. Clinicians are unable to predict dangerous behavior with greater than chance accuracy. Depression, schizophrenia, personality disorders, mania, paranoia, temporal lobe dysfunction, and organic mental states may be associated with acts of aggression. Impulse control disorders are characterized by physical abuse (usually of the aggressor’s domestic partner or children), by pathologic intoxication, by impulsive sexual activities, and by reckless driving. Anabolic steroid usage by athletes has been associated with increased tendencies toward violent behavior.

In the United States, a significant proportion of all violent deaths are alcohol-related. The ingestion of even small amounts of alcohol can result in pathologic intoxication that resembles an acute organic mental condition. Amphetamines, crack cocaine, and other stimulants are frequently associated with aggressive behavior. Phencyclidine is a drug commonly associated with violent behavior that is occasionally of a bizarre nature, partly due to lowering of the pain threshold. Domestic violence and rape are much more widespread than previously recognized. Awareness of the problem is to some degree due to increasing recognition of the rights of women and the understanding by women that they do not have to accept abuse. Acceptance of this kind of aggressive behavior inevitably leads to more, with the ultimate aggression being murder—20–50% of murders in the United States occur within the family. Police are called for more domestic disputes than all other criminal incidents combined. Children living in such family situations frequently become victims of abuse.

Features of individuals who have been subjected to long-term physical or sexual abuse are as follows: trouble expressing anger, staying angry longer, general passivity in relationships, feeling “marked for life” with an accompanying feeling of deserving to be victimized, lack of trust, and dissociation of affect from experiences. They are prone to express their psychological distress with somatization symptoms, often pain complaints. They may also have symptoms related to posttraumatic stress, as discussed above. The clinician should be suspicious about the origin of any injuries not fully explained, particularly if such incidents recur.

**Treatment**

**A. Psychological**

Management of any violent individual includes appropriate psychological maneuvers. Move slowly, talk slowly with clarity and reassurance, and evaluate the situation. Strive to create a setting that is minimally disturbing, and eliminate people or things threatening to the violent individual. Do not threaten or abuse, and do not touch or crowd the person. Allow no weapons in the area (an increasing problem in hospital emergency departments). Proximity to a door is comforting to both the patient and the examiner. Use a negotiator the violent person can relate to comfortably. Food and drink are helpful in defusing the situation (as are cigarettes for those who smoke). Honesty is important. Make no false promises, bolster the patient’s self-esteem, and continue to engage the subject verbally until the situation is under control. This type of individual does better with strong external controls to replace the lack of inner controls over the long term. Close probationary supervision and judicially mandated restrictions can be most helpful. There should be a major effort to help the individual avoid drug use (eg, Alcoholics Anonymous). Victims of abuse are essentially treated as any victim of trauma and, not infrequently, have evidence of PTSD.

**B. Pharmacologic**

Pharmacologic means are often necessary whether or not psychological approaches have been successful. This is particularly true in the agitated or psychotic patient. The drug of choice in psychotic aggressive states is haloperidol, 5–10 mg intramuscularly every hour until symptoms are alleviated. Benzodiazepine sedatives (eg, diazepam, 5 mg orally or intravenously every several hours) can be used for mild to moderate agitation, but an antipsychotic drug is preferred for management of the seriously violent and psychotic patient. Chronic aggressive states, particularly in retardation and brain damage (rule out causative organic conditions and medications such as anticholinergic medications in amounts sufficient to cause confusion), have been ameliorated with risperidone, 0.5–2 mg/d orally, propranolol, 40–240 mg/d orally, or pindolol, 5 mg twice daily orally (pindolol causes less bradycardia and hypotension than propranolol). Carbamazepine and valproic acid are effective in the treatment of aggression and explosive disorders, particularly when associated with known or suspected brain lesions. Lithium and SSRIs are also effective...
for some intermittent explosive outbursts. Buspirone (10–45 mg/d orally) is helpful for aggression, particularly in mentally retarded patients.

C. Physical

Physical management is necessary if psychological and pharmacologic means are not sufficient. It requires the active and visible presence of an adequate number of personnel (five or six) to reinforce the idea that the situation is under control despite the patient’s lack of inner controls. Such an approach often precludes the need for actual physical restraint. When adequate personnel are not available, however, two people shielded by a mattress (single-bed size) can usually corner and subdue the patient without injury to anyone. Seclusion rooms and restraints should be used only when necessary (ambulatory restraints are an alternative), and the patient must then be observed at frequent intervals. Design of corridors and seclusion rooms is important. Narrow corridors, small spaces, and crowded areas exacerbate the potential for violence in an anxious patient.

D. Other Interventions

The treatment of victims (eg, battered women) is challenging and often complicated by their reluctance to leave the situation. Reasons for staying vary, but common themes include the fear of more violence because of leaving, the hope that the situation may ameliorate (in spite of steady worsening), and the financial aspects of the situation, which are seldom to the woman’s advantage. Concerns for the children often finally compel the woman to seek help. An early step is to get the woman into a therapeutic situation that provides the support of others in similar straits. Al-Anon is frequently a valuable asset and quite appropriate when alcohol is a factor. The group can support the victim while she gathers strength to consider alternatives without being paralyzed by fear. Many cities now offer temporary emergency centers and counseling. Use the available resources, attend to any medical or psychiatric problems, and maintain a compassionate interest. Some states now require physicians to report injuries caused by abuse or suspected abuse to police authorities.

Substance Use Disorders (Drug Dependency, Drug Abuse)

The term “drug dependency” is used in a broad sense here to include both addictions and habituations. It involves the triad of compulsive drug use referred to as drug addiction, which includes: (1) a psychological dependence or craving and the behavior involved in procurement of the drug; (2) physiologic dependence, with withdrawal symptoms on discontinuance of the drug; and (3) tolerance, ie, the need to increase the dose to obtain the desired effects. Drug dependency is a function of the amount of drug used and the duration of usage. The amount needed to produce dependency varies with the nature of the drug and the idiosyncratic nature of the user. The frequency of use is usually daily, and the duration is inevitably > 2–3 weeks. Polydrug abuse is very common. Transgenerational continuity of drug abuse is also common.

There is accumulating evidence that an impairment syndrome exists in many former (and current) drug users. It is believed that drug use produces damaged neurotransmitter receptor sites and that the consequent imbalance produces symptoms that may mimic other psychiatric illnesses. “Kindling”—repeated stimulation of the brain—renders the individual more susceptible to focal brain activity with minimal stimulation. Stimulants and depressants can produce kindling, leading to relatively spontaneous effects no longer dependent on the original stimulus. These effects may be manifested as mood swings, panic, psychosis, and occasionally overt seizure activity. The imbalance also results in frequent job changes, marital problems, and generally erratic behavior. Patients with PTSD frequently have treated themselves with a variety of drugs. Chronic abusers of a wide variety of drugs exhibit cerebral atrophy on CT scans, a finding that may relate to the above symptoms. Early recognition is important, mainly to establish realistic treatment programs that are chiefly symptom-directed.

The clinician faces three problems with substance abuse: (1) the prescribing of substances such as sedatives, stimulants, or opioids that might produce dependency; (2) the treatment of individuals who have already abused drugs, most commonly alcohol; and (3) the detection of illicit drug use in patients presenting with psychiatric symptoms. The usefulness of urinalysis for detection of drugs varies markedly with different drugs and under different circumstances (pharmacokinetics is a major factor). Water-soluble drugs (eg, alcohol, stimulants, opioids) are eliminated in a day or so. Lipophilic substances (eg, barbiturates, tetrahydrocannabinol) appear in the urine over longer periods of time: several days in most cases, 1–2 months in chronic marijuana users. Sedative drug determinations are quite variable, amount of drug and duration of use being important determinants. False-positives can be a problem related to ingestion of some legitimate medications (eg, phenytoin for barbiturates, phenylpropanolamine for amphetamines, chlorpromazine for opioids) and some foods (eg, poppy seeds for opioids, coca leaf tea for cocaine). Manipulations can alter the legitimacy of the testing. Dilution, either in vivo or in vitro, can be detected by checking urine specific gravity. Addition of ammonia, vinegar, or salt may invalidate the test, but odor and pH determinations are simple. Hair analysis can determine drug use over longer periods, particularly sequential drug-taking patterns. The sensitivity and reliability of such tests are considered good, and the method may be complementary to urinalysis.
ALCOHOL DEPENDENCY & ABUSE (Alcoholism)

ESSENTIALS OF DIAGNOSIS

Major criteria:
- Physiologic dependence as manifested by evidence of withdrawal when intake is interrupted.
- Tolerance to the effects of alcohol.
- Evidence of alcohol-associated illnesses, such as alcoholic liver disease, cerebellar degeneration.
- Continued drinking despite strong medical and social contraindications and life disruptions.
- Impairment in social and occupational functioning.
- Depression.
- Blackouts.

Other signs:
- Alcohol stigmas: alcohol odor on breath, alcoholic facies, flushed face, scleral injection, tremor, ecchymoses, peripheral neuropathy.
- Surreptitious drinking.
- Unexplained work absences.
- Frequent accidents, falls, or injuries of vague origin; in smokers, cigarette burns on hands or chest.
- Laboratory tests: elevated values of liver function tests, mean corpuscular volume, serum uric acid, and triglycerides.

General Considerations

Alcoholism (also known as alcohol dependence) is a syndrome consisting of two phases: at-risk drinking and alcohol addiction. At-risk drinking is the repetitive use of alcohol, often to alleviate anxiety or solve other emotional problems. Alcohol addiction is a true addiction, similar to that which occurs following the repeated use of other sedatives. Symptoms of mild withdrawal, including tremor, elevated vital signs, and anxiety, begin within about 8 hours after the last drink and usually have passed by day 3. Generalized seizures occur within the first 24–38 hours and are more prevalent in persons who have a history of withdrawal syndromes. Delirium tremens is an acute organic psychosis that is usually manifest within 24–72 hours after the last drink (but may occur up to 7–10 days later). It is characterized by mental confusion, tremor, sensory hyperacuity, visual hallucinations (often of snakes, bugs, etc), autonomic hyperactivity, diaphoresis, dehydration, electrolyte disturbances (hypokalemia, hypomagnesemia), seizures, and cardiovascular abnormalities. The acute withdrawal syndrome is often completely unexpected and occurs when the patient has been hospitalized for some unrelated problem and presents as a diagnostic problem. Suspect alcohol withdrawal in every unexplained delirium. The mortality rate from delirium tremens has steadily decreased with early diagnosis and improved treatment.

Clinical Findings

A. Acute Intoxication

The signs of alcoholic intoxication are the same as those of overdosage with any other central nervous system depressant: drowsiness, errors of commission, psychomotor dysfunction, disinhibition, dysarthria, ataxia, and nystagmus. For a 70-kg person, an ounce of whiskey, a 4- to 6-oz glass of wine, or a 12-oz bottle of beer (roughly 15, 11, and 13 grams of alcohol, respectively) may raise the level of alcohol in the blood by 25 mg/dL. For a 50-kg person, the blood alcohol level would rise even higher (35 mg/dL) with the same consumption. Blood alcohol levels below 50 mg/dL rarely cause significant motor dysfunction (the legal limit for driving under the influence is commonly 80 mg/dL). Intoxication as manifested by ataxia, dysarthria, and nausea and vomiting indicates a blood level >150 mg/dL, and lethal blood levels range from 350 to 900 mg/dL. In severe cases, overdosage is marked by respiratory depression, stupor, seizures, shock syndrome, coma, and death. Serious overdoses are frequently due to a combination of alcohol with other sedatives.

B. Withdrawal

There is a wide spectrum of manifestations of alcoholic withdrawal, ranging from anxiety, decreased cognition, and tremulousness through increasing irritability and hyperreactivity to full-blown delirium tremens. Symptoms of mild withdrawal, including tremor, elevated vital signs, and anxiety, begin within about 8 hours after the last drink and usually have passed by day 3. Generalized seizures occur within the first 24–38 hours and are more prevalent in persons who have a history of withdrawal syndromes. Delirium tremens is an acute organic psychosis that is usually manifest within 24–72 hours after the last drink (but may occur up to 7–10 days later). It is characterized by mental confusion, tremor, sensory hyperacuity, visual hallucinations (often of snakes, bugs, etc), autonomic hyperactivity, diaphoresis, dehydration, electrolyte disturbances (hypokalemia, hypomagnesemia), seizures, and cardiovascular abnormalities. The acute withdrawal syndrome is often completely unexpected and occurs when the patient has been hospitalized for some unrelated problem and presents as a diagnostic problem. Suspect alcohol withdrawal in every unexplained delirium. The mortality rate from delirium tremens has steadily decreased with early diagnosis and improved treatment.
In addition to the immediate withdrawal symptoms, there is evidence of persistent longer-term ones, including sleep disturbances, anxiety, depression, excitability, fatigue, and emotional volatility. These symptoms may persist for 3–12 months, and in some cases they become chronic.

### C. Alcoholic (Organic) Hallucinosis

This syndrome occurs either during heavy drinking or on withdrawal and is characterized by a paranoid psychosis without the tumultuousness, confusion, and clouded sensorium seen in withdrawal syndromes. The patient appears normal except for the auditory hallucinations, which are frequently persecutory and may cause the patient to behave aggressively and in a paranoid fashion.

### D. Chronic Alcoholic Brain Syndromes

These encephalopathies are characterized by increasing erratic behavior, memory and recall problems, and emotional instability—the usual signs of organic brain injury due to any cause. Wernicke-Korsakoff syndrome due to thiamine deficiency may develop with a series of episodes. Wernicke encephalopathy consists of the triad of confusion, ataxia, and ophthalmoplegia (typically sixth nerve). Early recognition and treatment with thiamine can minimize damage. One of the possible sequelae is Korsakoff psychosis, characterized by both anterograde and retrograde amnesia, with confabulation early in the course. Early recognition and treatment of the alcoholic with intravenous thiamine and B complex vitamins can minimize damage.

### E. Laboratory Findings

Ethanol may contribute to the presence of an otherwise unexplained osmolar gap. There may also be elevated liver function tests, increased serum uric acid and triglycerides, and decreased serum potassium and magnesium. The most definitive biologic marker for chronic alcoholism is carbodextrate deficient transferrin, which can detect heavy use (60 mg/d over 7–10 days) with high specificity. Two other tests that may provide clues to an alcohol problem are γ-glutamyl transpeptidase measurement (levels > 30 units/L are suggestive of heavy drinking) and mean corpuscular volume (> 95 fL in men and > 100 fL in women). If both are elevated, a serious drinking problem is likely. Use of other recreational drugs with alcohol skews and negates the significance of these tests. High-density lipoprotein cholesterol elevations combined with elevated γ-glutamyl transpeptidase concentrations also can help identify heavy drinkers.

### Differential Diagnosis

The differential diagnosis of alcoholism is essentially between primary alcoholism (when no other major psychiatric diagnosis exists) and secondary alcoholism (when alcohol is used as self-medication for major underlying psychiatric problems such as schizophrenia or affective disorder). The differentiation is important, since the latter group requires treatment for the specific psychiatric problem. In primary and secondary alcoholism, at-risk drinking can be distinguished from alcohol addiction by taking a careful psychiatric history and evaluating the degree to which recurrent drinking impacts the social role functioning and physical safety of the individual.

The differential diagnosis of alcohol withdrawal includes other sedative withdrawals and other causes of delirium. Acute alcoholic hallucinosis must be differentiated from other acute paranoid states such as amphetamine psychosis or paranoid schizophrenia. The history and laboratory test results are the most important features in differentiating chronic organic brain syndromes due to alcohol from those due to other causes. The form of the brain syndrome is of little help—eg, chronic brain syndromes from lupus erythematosus may be associated with confabulation similar to that resulting from long-standing alcoholism.

### Complications

The medical, economic, and psychosocial problems of alcoholism are staggering. The central and peripheral nervous system complications include chronic brain syndromes, cerebellar degeneration, cardiomyopathy, and peripheral neuropathies. Direct effects on the liver include cirrhosis, esophageal varices, and eventual hepatic failure. Indirect effects include protein abnormalities, coagulation defects, hormone deficiencies, and an increased incidence of liver neoplasms.

**Fetal alcohol syndrome** includes one or more of the following developmental defects in the offspring of alcoholic women: (1) low birth weight and small size with failure to catch up in size or weight, (2) mental retardation, with an average IQ in the 60s, and (3) a variety of birth defects, with a large percentage of facial and cardiac abnormalities. The fetuses are very quiet in utero, and there is an increased frequency of breech presentations. There is a higher incidence of delayed postnatal growth and behavior development. The risk is appreciably higher the more alcohol ingested by the mother each day. Cigarette and marijuana smoking as well as cocaine use can produce similar effects on the fetus.

### Treatment of At-Risk Drinking

#### A. Psychological

The most important consideration for the clinician is to suspect the problem early and take a nonjudgmental attitude, although this does not mean a passive one. The problem of denial must be faced, preferably with significant family members at the first meeting. This means dealing from the beginning with any enabling behavior of the spouse or other significant people. Enabling behavior allows the alcoholic to avoid facing the consequences of his or her behavior.

There must be an emphasis on the things that can be done. This approach emphasizes the fact that the clinician cares and strikes a positive and hopeful note early in treatment. Valuable time should not be wasted trying to find out why the patient drinks; come to grips early with the immediate problem of how to stop the drinking. Although total abstinence should be the ultimate goal, a harm reduction model indicates that gradual progress toward abstinence can be a useful treatment stratagem.

**Motivational interviewing**, a model of counseling that addresses both the patient’s ambivalence and motivation for change, may contribute to reduced consumption over time.
B. Social

Get the patient into Alcoholics Anonymous and the spouse into Al-Anon. Success is usually proportionate to the utilization of Alcoholics Anonymous, religious counseling, and other resources. The patient should be seen frequently for short periods and charged an appropriate fee.

Do not underestimate the importance of religion, particularly since the alcoholic is often a dependent person who needs a great deal of support. Early enlistment of the help of a concerned religious adviser can often provide the turning point for a personal conversion to sobriety.

One of the most important considerations is the patient’s job—fear of losing a job is one of the most powerful motivations for giving up drink. The business community has become painfully aware of the problem, with the result that about 70% of the Fortune 500 companies offer programs to their employees to help with the problem of alcoholism. In the latter case, some specific recommendations to employers can be offered: (1) Avoid placement in jobs where the alcoholic must be alone, e.g., as a traveling buyer or sales executive. (2) Use supervision but not surveillance. (3) Keep competition with others to a minimum. (4) Avoid positions that require quick decision-making on important matters (high-stress situations). In general, commitment to abstinence and avoidance of situations that might be conducive to drinking are most predictive of a good outcome.

C. Medical

Hospitalization is not usually necessary. It is sometimes used to dramatize a situation and force the patient to face the problem of alcoholism, but generally it should be used for medical indications.

Because of the many medical complications of alcoholism, a complete physical examination with appropriate laboratory tests is mandatory, with special attention to the liver and nervous system. Use of sedatives as a replacement for alcohol is not desirable. The usual result is concomitant use of sedatives and alcohol and worsening of the problem. Lithium is not helpful in the treatment of alcoholism.

Disulfiram (250–500 mg/d orally) has been used for many years as an aversive drug to discourage alcohol use. Disulfiram inhibits alcohol dehydrogenase, causing toxic reactions when alcohol is consumed. The results have generally been of limited effectiveness and depend on the motivation of the individual to be compliant.

Naltrexone, an opiate antagonist, in a dosage of 50 mg orally daily, has been helpful in lowering relapse rates over the 3–6 months after cessation of drinking, apparently by lessening the pleasurable effects of alcohol. One study suggests that naltrexone is most effective when given during periods of drinking in combination with therapy that supports abstinence but accepts the fact that relapses occur. Naltrexone is FDA-approved for maintenance therapy. Studies indicate that it reduces alcohol craving when used as part of a comprehensive treatment program. Acamprosate (333–666 mg orally three times daily) helps reduce craving and maintain abstinence, and can be continued even during periods of relapse.

D. Behavioral

Conditioning approaches historically have been used in some settings in the treatment of alcoholism, most commonly as a type of aversion therapy. For example, the patient is given a drink of whiskey and then a shot of apomorphine, and proceeds to vomit. In this way a strong association is built up between the drinking and vomiting. Although this kind of treatment has been successful in some cases, after appropriate informed consent, many people do not sustain the learned aversive response.

Treatment of Hallucinosis & Withdrawal

A. Medical

1. Alcoholic hallucinosis—Alcoholic hallucinosis, which can occur either during or on cessation of a prolonged drinking period, is not a typical withdrawal syndrome and is handled differently. Since the symptoms are primarily those of a psychosis in the presence of a clear sensorium, they are handled like any other psychosis: hospitalization (when indicated) and adequate amounts of antipsychotic medications. Haloperidol, 5 mg orally twice a day for the first day or so, usually ameliorates symptoms quickly, and the drug can be decreased and discontinued over several days as the patient improves. It then becomes necessary to deal with the chronic alcohol abuse, which has been discussed.

2. Withdrawal symptoms—The onset of withdrawal symptoms is usually 8–12 hours and the peak intensity of symptoms is 48–72 hours after alcohol consumption is stopped. Providing adequate central nervous system depressants (eg, benzodiazepines) is important to counteract the excitability resulting from sudden cessation of alcohol intake. The choice of a specific sedative is less important than using adequate doses to bring the patient to a level of moderate sedation, and this will vary from person to person. Mild dependency requires “drying out.”

In some instances for outpatients, a short course of tapering long-acting benzodiazepines—eg, diazepam, 20 mg orally daily initially, decreasing by 5 mg daily—may be a useful adjunct. In moderate to severe withdrawal, hospitalize the patient and use diazepam orally in a dosage of 5–10 mg hourly depending on the clinical need as judged by withdrawal symptoms, including nausea, tremor, autonomic hyperactivity, agitation; tactile, visual, and auditory hallucinations; and disorientation. This type of symptom-driven medication regimen for withdrawal appears to reduce total benzodiazepine usage over fixed-dose schedules. Antipsychotic medications should not be used. Monitoring of vital signs and fluid and electrolyte levels is essential for the severely ill patient.

In very severe withdrawal, intravenous administration is necessary. After stabilization, the amount of diazepam required to maintain a sedated state may be given orally every 8–12 hours. If restlessness, tremulousness, and other signs of withdrawal persist, the dosage is increased until moderate sedation occurs. The dosage is then gradually reduced by 20% every 24 hours until withdrawal is complete. This usually requires a week or so of treatment. Clonidine, 5 mcg/kg orally every 2 hours, or the patch
formulation of appropriate dosage strength, suppresses cardiovascular signs of withdrawal and has some anxiolytic effect. Carbamazepine, 400–800 mg daily orally, compares favorably with benzodiazepines for alcohol withdrawal.

Atenolol, as an adjunct to benzodiazepines, can reduce symptoms of alcohol withdrawal. The daily oral atenolol dose is 100 mg when the heart rate is above 80 beats per minute and 50 mg for a heart rate between 50 and 80 beats per minute. Atenolol should not be used when bradycardia is present.

Meticulous examination for other medical problems is necessary. Alcoholic hypoglycemia can occur with low blood alcohol levels (see Chapter 27). Alcoholics commonly have liver disease and associated clotting problems and are also prone to injury—and the combination all too frequently leads to undiagnosed subdural hematoma.

Phenytoin does not appear to be useful in managing alcohol withdrawal seizures per se. Sedating doses of benzodiazepines are effective in treating alcohol withdrawal seizures. Thus, other anticonvulsants are not usually needed unless there is a preexisting seizure disorder.

A general diet should be given, and vitamins in high doses: thiamine, 50 mg intravenously initially, then intramuscularly on a daily basis; pyridoxine, 100 mg/d; folic acid, 1 mg/d; and ascorbic acid, 100 mg twice a day. Intravenous glucose solutions should not be given prior to thiamine for fear of precipitating Wernicke syndrome. Thiamine is necessary as a ketolase enzyme cofactor. Concurrent administration of vitamins is satisfactory, and hydration should be meticulously assessed on an ongoing basis.

Chronic brain syndromes secondary to a long history of alcohol intake are not clearly responsive to thiamine and vitamin replenishment. Attention to the social and environmental care of this type of patient is paramount.

B. Psychological and Behavioral

The comments in the section on problem drinking apply here also; these methods of treatment become the primary consideration after successful treatment of withdrawal or alcoholic hallucinosis. Psychological and social measures should be initiated in the hospital prior to discharge. This increases the possibility of continued post-hospitalization treatment.

OTHER DRUG & SUBSTANCE DEPENDENCIES

1. Opioids

While the terms “opioids” and “narcotics” both refer to a group of drugs with actions that mimic those of morphine, the term “opioids” is used when discussing medications prescribed in a controlled manner by a clinician, and the term “narcotics” is used to connote illicit drug use. The group includes natural derivatives of opium (opiates), synthetic surrogates (opioids), and a number of polypeptides, some of which have been discovered to be natural neurotransmitters. The principal narcotic of abuse is heroin (metabolized to morphine), which is not used as a legitimate medication. The other common opioids are prescription medications that differ in milligram potency, duration of action, and agonist and antagonist capabilities (see Chapter 5). All of the opioid analgesics can be reversed by the opioid antagonist naloxone.

The clinical symptoms and signs of mild narcotic intoxication include changes in mood, with feelings of euphoria; drowsiness; nausea with occasional emesis; needle tracks; and miosis. The incidence of snorting and inhalating heroin ("smoking") is increasing, particularly among cocaine users. This coincides with a decrease in the availability of methaqualone (no longer marketed) and other sedatives used to temper the cocaine "high" (see discussion of cocaine under Stimulants, below). Overdoses cause respiratory depression, peripheral vasodilation, pinpoint pupils, pulmonary edema, coma, and death.

Dependence is a major concern when continued use of opioids occurs, although withdrawal causes only moderate morbidity (similar in severity to a bout of "flu"). Addicted patients sometimes consider themselves more addicted than they really are and may not require a withdrawal program. Grades of withdrawal are categorized from 0 to 4: grade 0 includes craving and anxiety; grade 1, yawning, lacrimation, rhinorrhea, and perspiration; grade 2, previous symptoms plus mydriasis, piloerection, anorexia, tremors, and hot and cold flashes with generalized aching; grades 3 and 4, increased intensity of previous symptoms and signs, with increased temperature, blood pressure, pulse, and respiratory rate and depth. In withdrawal from the most severe addiction, vomiting, diarrhea, weight loss, hemococoncentration, and spontaneous ejaculation or orgasm commonly occur. Complications of heroin administration include infections (eg, pneumonia, septic emboli, hepatitis, and HIV infection from using nonsterile needles), traumatic insults (eg, arterial spasm due to drug injection, gangrene), and pulmonary edema.

Treatment for overdosage (or suspected overdosage) is naloxone, 2 mg intravenously. If an overdose has been taken, the results are dramatic and occur within 2 minutes. Since the duration of action of naloxone is much shorter than that of the opioids, the patient must be under close observation. Hospitalization, supportive care, repeated naloxone administration, and observation for withdrawal from other drugs should be maintained for as long as necessary.

Treatment for withdrawal begins if grade 2 signs develop. If a withdrawal program is necessary, use methadone, 10 mg orally (use parenteral administration if the patient is vomiting), and observe. If signs (piloerection, mydriasis, cardiovascular changes) persist for >4–6 hours, give another 10 mg; continue to administer methadone at 4- to 6-hour intervals until signs are not present (rarely > 40 mg of methadone in 24 hours). Divide the total amount of drug required over the first 24-hour period by 2...
and give that amount every 12 hours. Each day, reduce the total 24-hour dose by 5–10 mg. Thus, a moderately addicted patient initially requiring 30–40 mg of methadone could be withdrawn over a 4- to 8-day period. Clonidine, 0.1 mg orally several times daily over a 10- to 14-day period, is both an alternative and an adjunct to methadone detoxification; it is not necessary to taper the dose. Clonidine is helpful in alleviating cardiovascular symptoms but does not significantly relieve anxiety, insomnia, or generalized aching. There is a protracted abstinence syndrome of metabolic, respiratory, and blood pressure changes over a period of 3–6 months.

Opioid antagonists (eg, naltrexone) can also be used successfully for treatment of the patient who has been free of opioids for 7–10 days. Naltrexone blocks the narcotic “high” of heroin when 50 mg is given orally every 24 hours initially for several days and then 100 mg is given every 48–72 hours. A monthly injectable form of naltrexone has become available and may enhance compliance. Liver disorders are a major contraindication. Buprenorphine, a partial agonist, has become a mainstay of office-based treatment of opiate dependency. Its use requires certified training.

Alternative strategies for the treatment of opioid withdrawal have included rapid and ultrarapid detoxification techniques. However, recent data do not support the use of either method. Methadone maintenance programs are of some value in chronic recidivism. Under carefully controlled supervision, the narcotic addict is maintained on fairly high doses of methadone (40–120 mg/d) that satisfy craving and block the effects of heroin to a great degree.

2. Sedatives (Anxiolytics)

See Anxiety Disorders, this chapter.

3. Psychedelics

About 6000 species of plants have psychoactive properties. All of the common psychedelics (LSD, mescaline, psilocybin, dimethyltryptamine, and other derivatives of phenylalanine and tryptophan) can produce similar behavioral and physiologic effects. An initial feeling of tension is followed by emotional release such as crying or laughing (1–2 hours). Later, perceptual distortions occur, with visual illusions and hallucinations, and occasionally there is fear of ego disintegration (2–3 hours). Major changes in time sense and mood lability then occur (3–4 hours). A feeling of detachment and a sense of destiny and control occur (4–6 hours). Of course, reactions vary among individuals, and some of the drugs produce markedly different time frames. Occasionally, the acute episode is terrifying (a “bad trip”), which may include panic, depression, confusion, or psychotic symptoms. Preexisting emotional problems, the attitude of the user, and the setting where the drug is used affect the experience.

Treatment of the acute episode primarily involves protection of the individual from erratic behavior that may lead to injury or death. A structured environment is usually sufficient until the drug is metabolized. In severe cases, antipsychotic medications with minimal side effects (eg, haloperidol, 5 mg intramuscularly) may be given every several hours until the individual has regained control. In cases where “flashbacks” occur (mental imagery from a “bad trip” that is later triggered by mild stimuli such as marijuana, alcohol, or psychic trauma), a short course of an antipsychotic drug—eg, olanzapine, 5–10 mg/d, or risperidone, 2 mg/d, initially, and up to 20 mg/d and 6 mg/d, respectively—is usually sufficient. Lorazepam, 1–2 mg orally or intramuscularly every 2 hours as needed for acute agitation, may be a useful adjunct. An occasional patient may have “flashbacks” for much longer periods and require small doses of neuroleptic medications over the longer term.

4. Phencyclidine

Phencyclidine (PCP, angel dust, peace pill, hog), developed as an anesthetic agent, first appeared as a street drug deceptively sold as tetrahydrocannabinol (THC). Because it is simple to produce and mimics to some degree the traditional psychedelic drugs, PCP has become a common deceptive substitute for LSD, THC, and mescaline. It is available in crystals, capsules, and tablets to be inhaled, injected, swallowed, or smoked (it is commonly sprinkled on marijuana).

Absorption after smoking is rapid, with onset of symptoms in several minutes and peak symptoms in 15–30 minutes. Mild intoxication produces euphoria accompanied by a feeling of numbness. Moderate intoxication (5–10 mg) results in disorientation, detachment from surroundings, distortion of body image, combativeness, unusual feats of strength (partly due to its anesthetic activity), and loss of ability to integrate sensory input, especially touch and proprioception. Physical symptoms include dizziness, ataxia, dysarthria, nystagmus, retracted upper eyelid with blank stare, hyperreflexia, and tachycardia. There are increases in blood pressure, respiration, muscle tone, and urine production. Usage in the first trimester of pregnancy is associated with an increase in spontaneous abortion and congenital defects. Severe intoxication (20 mg or more) produces an increase in degree of moderate symptoms, with the addition of seizures, deepening coma, hypertensive crisis, and severe psychotic ideation. The drug is particularly long-lasting (several days to several weeks) owing to high lipid solubility, gastrointestinal recycling, and the production of active metabolites. Overdosage may be fatal, with the major causes of death being hypertensive crisis, respiratory arrest, and convulsions. Acute rhabdomyolysis has been reported and can result in myoglobinuric kidney failure.

Differential diagnosis involves the whole spectrum of street drugs, since in some ways phencyclidine mimics sedatives, psychedelics, and marijuana in its effects. Blood and urine testing can detect the acute problem.

Treatment is discussed in Chapter 38.

5. Marijuana

Cannabis sativa, a hemp plant, is the source of marijuana. The parts of the plant vary in potency. The resinous exudate of the flowering tops of the female plant (hashish, charas) is the most potent, followed by the dried leaves and flowering shoots of the female plant (bhang) and the resinous mass from small leaves of inflowrescence (ganja). The least potent
6. Stimulants: Amphetamines & Cocaine

Stimulant abuse is quite common, either alone or in combination with abuse of other drugs. The stimulants include illicit drugs such as methamphetamine (“speed”)—one variant is a smokable form called “ice,” which gives an intense and fairly long-lasting high—and methylphenidate and dextroamphetamine, which are under prescription control. Street availability of amphetamines remains high. Moderate usage of any of the stimulants produces hyperactivity, a sense of enhanced physical and mental capacity, and sympathomimetic effects. The clinical picture of acute stimulant intoxication includes sweating, tachycardia, elevated blood pressure, mydriasis, hyperactivity, and an acute brain syndrome with confusion and disorientation. Tolerance develops quickly, and, as the dosage is increased, hypervigilance, paranoid ideation (with delusions of parasitosis), stereotypy, bruxism, tactile hallucinations of insect infestation, and full-blown psychoses occur, often with persecutory ideation and aggressive responses. Stimulant withdrawal is characterized by depression with symptoms of hyperphagia and hypersomnia.

People who have used stimulants chronically (eg, anorexigenics) occasionally become sensitized (“kindling”) to future use of stimulants. In these individuals, even small amounts of mild stimulants such as caffeine can cause symptoms of paranoia and auditory hallucinations. Cocaine is a stimulant. It is a product of the coca plant. The derivatives include seeds, leaves, coca paste, cocaine hydrochloride, and the free base of cocaine. Cocaine hydrochloride is the salt and the most commonly used form. Free base, a purer (and stronger) derivative called “crack,” is prepared by simple extraction from cocaine hydrochloride.

There are various modes of use. Coca leaf chewing involves chewing the leaves and chewing with alkaline material (eg, the ash of other burned leaves) to enhance buccal absorption. One achieves a mild high, with onset in 5–10 minutes and lasting for about an hour. Intranasal use is simply snorting cocaine through a straw. Absorption is slowed somewhat by vasoconstriction (which may eventually cause tissue necrosis and septal perforation); the onset of action is in 2–3 minutes, with a moderate high (euphoria, excitement, increased energy) lasting about 30 minutes. The purity of the cocaine is a major determinant of the high. Intravenous use of cocaine hydrochloride or “free base” is effective in 30 seconds and produces a short-lasting, fairly intense high of about 15 minutes’ duration. The combined use of cocaine and ethanol results in the metabolic production of cocaethylene by the liver. This substance produces more intense and long-lasting cocaine-like effects. Smoking freebase (volatilized cocaine because of the lower boiling point) acts in seconds and results in intense high lasting several minutes. The intensity of the reaction is related to the marked lipid solubility of the freebase form and produces by far the most severe medical and psychiatric symptoms.

Cardiovascular collapse, arrhythmias, myocardial infarction, and transient ischemic attacks have been reported. Seizures, strokes, migraine symptoms, hyperthermia, and lung damage may occur, and there are several obstetric complications, including spontaneous abortion, abruptio placenta, teratogenic effects, delayed fetal growth, and prematurity. Cocaine can cause anxiety, mood swings, and delirium, and chronic use can cause the same problems as other stimulants (see above).

Clinicians should be alert to cocaine use in patients presenting with unexplained nasal bleeding, headaches, fatigue, insomnia, anxiety, depression, and chronic hoarseness. Sudden withdrawal of the drug is not life-threatening but usually produces craving, sleep disturbances, hyperphagia, lassitude, and severe depression (sometimes with suicidal ideation) lasting days to weeks. Treatment is imprecise and difficult. Since the high is related to blockade of dopamine uptake, the dopamine agonist bromocriptine, 1.5 mg orally three times a day, alleviates some of the symptoms of craving associated with acute cocaine withdrawal. Other dopamine agonists such as apomorphine, levodopa, and amantadine are under study for this purpose. Carbamazepine may be a useful adjunct in treating symptoms of alcohol withdrawal, and desipramine in moderate doses has been useful in helping maintain abstinence in the early stages of treatment.
Treatment of psychosis is the same as that of any psychosis: antipsychotic medications in dosages sufficient to alleviate the symptoms. Any medical symptoms (eg, hyperthermia, seizures, hypertension) are treated specifically. These approaches should be used in conjunction with a structured program, most often based on the Alcoholics Anonymous model. Hospitalization may be required if self-harm or violence toward others is a perceived threat (usually indicated by paranoid delusions).

7. Caffeine

Caffeine, along with nicotine and alcohol, is one of the most commonly used drugs worldwide. About 10 billion pounds of coffee (the richest source of caffeine) are consumed yearly throughout the world. Tea, cocoa, and cola drinks also contribute to an intake of caffeine that is often astoundingly high in a large number of people. Low to moderate doses (30–200 mg/d) tend to improve some aspects of performance (eg, vigilance). The approximate content of caffeine in a (180-mL) cup of beverage is as follows: brewed coffee, 80–140 mg; instant coffee, 60–100 mg; decaffeinated coffee, 1–6 mg; black leaf tea, 30–80 mg; tea bags, 25–75 mg; instant tea, 30–60 mg; cocoa, 10–50 mg; and 12-oz cola drinks, 30–65 mg. A 2-oz chocolate candy bar has about 20 mg. Some herbal teas (eg, “morning thunder”) contain caffeine. Caffeine-containing analgesics usually contain approximately 30 mg per unit. Symptoms of caffeineism (usually associated with ingestion of over 500 mg/d) include anxiety, agitation, restlessness, insomnia, a feeling of being “wired,” and somatic symptoms referable to the heart and gastrointestinal tract. It is common for a case of caffeineism to present as an anxiety disorder. It is also common for caffeine and other stimulants to precipitate severe symptoms in compensated schizophrenic and manic-depressive patients. Chronically depressed patients often use caffeine drinks as self-medication. This diagnostic clue may help distinguish some major affective disorders. Withdrawal from caffeine (> 250 mg/d) can produce headaches, irritability, lethargy, and occasional nausea.

8. Miscellaneous Drugs, Solvents

The principal over-the-counter drugs of concern have been phenylpropanolamine and an assortment of antihistaminic agents, frequently in combination with a mild analgesic promoted as cold remedies. Medications containing phenylpropanolamine have been removed from sale in the United States due to an FDA ban. The major problem in use of phenylpropanolamine relates to its side effects as a stimulant, including precipitation of anxiety states, increased blood pressure effects, auditory and visual hallucinations, paranoid ideation, and occasionally delirium. Aggressiveness and some loss of impulse control were reported as well as sleep disturbances even with small doses.

Antihistamines usually produce some central nervous system depression—thus their use as over-the-counter sedatives. Practically all of the so-called sleep aids are antihistamines. The mixture of antihistamines with alcohol usually exacerbates the central nervous system effects. Scopolamine and bromides have generally been removed from over-the-counter products.

The abuse of laxatives sometimes can lead to electrolyte disturbances that may contribute to the manifestations of a delirium. The greatest use of laxatives tends to be in the elderly and in those with eating disorders, both of whom are the most vulnerable to physiologic changes.

Anabolic steroids are being abused by people who wish to increase muscle mass for cosmetic reasons or for greater strength. In addition to the medical problems, the practice is associated with significant mood swings, aggressiveness, and paranoid delusions. Alcohol and stimulant use is higher in these individuals. Withdrawal symptoms of steroid dependency include fatigue, depressed mood, restlessness, and insomnia.

Amyl nitrite has been used as an “orgasm expander.” The changes in time perception, “rush,” and mild euphoria caused by the drug prompted its nonmedical use, and popular lore concerning the effects of inhalation just prior to orgasm has led to increased use. Subjective effects last from 5 seconds to 15 minutes. Tolerance develops readily, but there are no known withdrawal symptoms. Abstinence for several days reestablishes the previous level of responsiveness. Long-term effects may include damage to the immune system and respiratory difficulties.

Sniffing of solvents and inhaling of gases (including aerosols) produce a form of inebriation similar to that of the volatile anesthetics. Agents include gasoline, toluene, petroleum ether, lighter fluids, cleaning fluids, paint thinners, and solvents that are present in many household products (eg, nail polish, typewriter correction fluid). Typical intoxication states include euphoria, slurred speech, hallucinations, and confusion, and with high doses, acute manifestations are unconsciousness and cardiopulmonary depression or failure; chronic exposure produces a variety of symptoms related to the liver, kidney, bone marrow, or heart. Lead encephalopathy can be associated with sniffing leaded gasoline. In addition, studies of workers chronically exposed to jet fuel showed significant increases in neurototoxic symptoms, including fatigue, anxiety, mood changes, memory difficulties, and somatic complaints. These same problems have been noted in long-term solvent abuse.

The so-called designer drugs are synthetic substitutes for commonly used recreational drugs and are produced in small, clandestine laboratories. The most common designer drugs have been methyl analogues of fentanyl and have been used as heroin substitutes. MDMA (methylene-dioxymethamphetamine), an amphetamine derivative sometimes called “ecstasy,” is also a designer drug with high abuse potential and neurotoxicity. Often not detected by standard toxicology screens, these substances can present a vexing problem for clinicians faced with symptoms from a totally unknown cause.

the cognitive disorders show some degree of impaired thinking depending on the site of involvement, the rate of onset and progression, and the duration of the underlying brain lesion. Emotional disturbances (eg, depression) are often present as significant comorbidities. The behavioral disturbances tend to be more common with chronicity, more directly related to the underlying personality or central nervous system vulnerability to drug side effects, and not necessarily correlated with cognitive dysfunction.

The causes of cognitive disorders are listed in Table 25–11.

**Clinical Findings**

The manifestations are many and varied and include problems with orientation, short or fluctuating attention span, loss of recent memory and recall, impaired judgment, emotional lability, lack of initiative, impaired impulse control, inability to reason through problems, depression (worse in mild to moderate types), confabulation (not limited to alcohol organic brain syndrome), constriction of intellectual functions, visual and auditory hallucinations, and delusions. Physical findings will naturally vary according to the cause. The electroencephalogram usually shows generalized slowing in delirium.

**General Considerations**

The organic problem may be a primary brain disease or a secondary manifestation of some general disorder. All of

A. Delirium

Delirium (acute confusional state) is a transient global disorder of attention, with clouding of consciousness, usually a result of systemic problems (eg, medications, hypoxemia). Onset is usually rapid. The mental status fluctuates (impairment is usually least in the morning), with varying inability to concentrate, maintain attention, and sustain purposeful behavior. There is a marked deficit of short-term memory and recall. Anxiety and irritability are common. Amnesia is retrograde (impaired recall of past memories) and anterograde (inability to recall events after the onset of the delirium). Orientation problems follow the inability to retain information. Perceptual disturbances (often visual hallucinations) and psychomotor restlessness with insomnia are common. Autonomic changes include tachycardia, dilated pupils, and sweating. The average duration is about 1 week, with full recovery in most cases. Delirium can coexist with dementia. Delirium may be hypoactive, hyperactive, or mixed. “Sundowning”—mild to moderate delirium at night—is more common in patients with preexisting dementia and may be precipitated by hospitalization, medications, and sensory deprivation.

Terminal delirium occurs commonly at the end of life. The delirium may be related to multiple medical causes, including organ failure, and may be unrecognized. Treatment must be based on a careful evaluation of the underlying etiology and the risks and benefits of available medical and nonmedical interventions.

B. Dementia

(See Chapters 4 and 24.) Dementia is characterized by chronicity and deterioration of selective mental functions. Specific cognitive assessment must be performed, since many patients are able to cover a deficit in routine conversation. The Mini-Mental State Examination produces a numerical score with up to 30 points given for correct answers to questions (likely organic < 27 points).

In all types of dementia, loss of impulse control (sexual and language) is common. The tenuous level of functioning makes the individual most susceptible to minor physical and psychological stresses. Pseudodementia is a term applied to depressed patients who appear to be demented. These patients are often identifiable by their tendency to complain about memory problems vociferously rather than try to cover them up. They usually say they cannot complete cognitive tasks but with encouragement can often do so. They can be considered to have depression-induced reversible dementia that remits when the depression resolves.

C. Amnestic Syndrome

This is a memory disturbance without delirium or dementia. It is usually associated with thiamine deficiency and chronic alcohol use (eg, Korsakoff syndrome). There is an impairment in the ability to learn new information or recall previously learned information.

D. Substance-Induced Hallucinosis

This condition is characterized by persistent or recurrent hallucinations (usually auditory) without the other symptoms usually found in delirium or dementia. Alcohol or hallucinogens are often the cause. There does not have to be any other mental disorder, and there may be complete spontaneous resolution.

E. Personality Changes Due to a General Medical Condition (Formerly Organic Personality Syndrome)

This syndrome is characterized by emotional lability and loss of impulse control along with a general change in personality. Cognitive functions are preserved. Social inappropriateness is common. Loss of interest and lack of concern with the consequences of one’s actions are often present. The course depends on the underlying cause (eg, frontal lobe contusion may resolve completely).

Differential Diagnosis

The differential diagnosis consists mainly of schizophrenia and the other psychoses, which are sometimes confused with cognitive disorders and are often accompanied by psychotic symptoms.

Complications

Chronicity may result from delayed correction of the defect, eg, subdural hematoma, low-pressure hydrocephalus. Accidents secondary to impulsive behavior and poor judgment are a major consideration. Secondary depression and impulsive behavior not infrequently lead to suicide attempts. Medications—particularly sedatives—may worsen thinking abilities and contribute to the overall problems.

Treatment

A. Medical

Delirium should be considered a syndrome of acute brain dysfunction analogous to acute kidney failure. The first aim of treatment is to identify and correct the etiologic medical problem. Evaluation should consist of a comprehensive physical examination including a search for neurologic abnormalities, infection, or hypoxia. Routine laboratory tests may include serum electrolytes, serum glucose, BUN, serum creatinine, liver function tests, thyroid function tests, arterial blood gases, complete blood count, serum calcium, phosphorus, magnesium, vitamin B12, folate, blood cultures, urinalysis, and cerebrospinal fluid analysis. Discontinue medications that may be contributing to the problem (eg, analgesics, corticosteroids, cimetidine, lidocaine, anticholinergic medications, central nervous system depressants, mefloquine). Do not overlook any possibility of reversible organic disease. Electroencephalography, CT, and MRI evaluations of the brain may be helpful in diagnosis. Ideally, the patient should be monitored without further medications while the evaluation is carried out. There are, however, two indications for medication in delirious states: behavioral control (eg, pulling out lines) and subjective distress (eg, pronounced fear due to hallucinations). If these indications are present, medications may be used. If there is any
Hint of alcohol or substance withdrawal (the most common cause of delirium in the general hospital), a benzodiazepine such as lorazepam (1–2 mg every hour) can be given parenterally. If there is little likelihood of withdrawal syndrome, haloperidol is often used in doses of 1–10 mg every hour. Given intravenously under ECG monitoring, it appears to impose slight risk of extrapyramidal side effects. In addition to the medication, a pleasant, comfortable, nonthreatening, and physically safe environment with adequate nursing or attendant services should be provided. Once the underlying condition has been identified and treated, adjunctive medications can be tapered.

Treatment of the behavioral manifestations of the dementia syndrome usually involve trying to positively reinforce healthy behaviors and not reinforcing maladaptive behaviors (such as aggression). Arranging the physical environment to maximize autonomy as much as feasible and promote regularity of routine, helps the individual cope with their limited intellectual reserves. Simple, direct statements are more easily comprehended by these individuals. Understanding how their decreased cognitive function limits their abilities is important. For example, one elderly man in a residential apartment kept complaining that someone was stealing his ice cream at night. Realizing that he was unable to recall eating it himself, his “delusion” made a certain sense. Once his caregivers understood this, they were able to be more compassionate in listening to his complaints and less worried about an ice cream burglar.

Aggressiveness and rage states in dementia can be reduced with lipophilic β-blockers (eg, propranolol, metoprolol) in moderate doses. Since the serotonergic system has been implicated in arousal conditions, medications that affect serotonin have been found to be of some benefit in aggression and agitation. Included in this group are lithium, trazodone, buspironone, and clonazepam. Dopamine blockers (eg, the neuroleptic medications such as haloperidol) have been used for many years to attenuate aggression. Atypical neuroleptics may have a role in selected geriatric patients; however, there are reports of increased mortality in some studies related to the use of atypical neuroleptics (equaling the elevated mortality of the typical agents) in this population. There are also reports of reduced agitation in Alzheimer disease from carbamazepine, 100–400 mg/d orally (with slow increase as needed). Emotional lability in some cases responds to small doses of imipramine (25 mg orally one to three times per day) or fluoxetine (5–20 mg/d orally); depression, which often occurs early in the course of Alzheimer dementia, responds to the usual doses of antidepressant medications, preferably those with the least anticholinergic side effects (eg, SSRIs and MAO inhibitors).

Ergotoxine alkaloids (ergoloid mesylates: Hydergine, others) have been studied with mixed results; improvement in ambulatory self-care and depressed mood has been noted, but there has been no improvement of cognitive functioning on any standardized tests. Stimulant medications (eg, methylphenidate) do not change cognitive function but can improve affect and mood, which helps the caretakers cope with the problem.

B. Social

Substitute home care, board and care, or convalescent home care may be most useful when the family is unable to care for the patient. The setting should include familiar people and objects, lights at night, and a simple schedule. Counseling may help the family to cope with problems and may help keep the patient at home as long as possible. Information about local groups can be obtained from the Alzheimer’s Disease and Related Disorders Association, 70 East Lake Street, Suite 600, Chicago, IL 60601. Volunteer services, including homemakers, visiting nurses, and adult protective services, may be helpful in maintaining the patient at home.

C. Behavioral

Behavioral techniques include operant responses that can be used to induce positive behaviors, eg, paying attention to the patient who is trying to communicate appropriately, and extinction by ignoring inappropriate responses. Patients with Alzheimer disease can learn skills and retain them but do not recall the circumstances in which they were learned.

D. Psychological

Formal psychological therapies are not usually helpful and may make things worse by taxing the patient’s limited cognitive resources.

> Prognosis

The prognosis is good for recovery of mental functioning in delirium when the underlying condition is reversible. For most dementia syndromes, the prognosis is for gradual deterioration, although new drug treatments may prove helpful.

3. Anxiety as an intrinsic aspect of the medical problem (eg, hyperthyroidism).
4. Denial of illness, which may present during acute or intermediate phases of illness.

B. Intermediate Problems

1. Depression as a function of the illness or acceptance of the illness, often associated with realistic or fantasized hopelessness about the future.
2. Behavioral problems, often related to denial of illness and, in extreme cases, causing the patient to leave the hospital against medical advice.

C. Recuperative Problems

1. Decreasing cooperation as the patient sees that improvement and compliance are not compelled.
2. Readjustment problems with family, job, and society.

General Considerations

A. Acute Problems

1. “Intensive care unit psychosis”—The stressful ICU environment may be a cause of delirium. Critical care unit factors include sleep deprivation, increased arousal, mechanical ventilation, and social isolation. Other causes include those common to delirium and require vigorous investigation (see Delirium, above).

2. Presurgical and postsurgical anxiety states—Such problems are common and commonly ignored. Presurgical anxiety is very common and is principally a fear of death (many surgical patients make out their wills). Patients may be fearful of anesthesia (improved by the preoperative anesthesia interview), the mysterious operating room, and the disease processes that might be uncovered by the surgeon. Such fears frequently cause people to delay examinations that might result in earlier surgery and a greater chance of cure.

The opposite of this is surgery proneness, the quest for surgery to escape from overwhelming life stresses. Polysurgery patients may be classified as having factitious disorders. Dynamic motivations include the need to get medical care as a way of getting dependency needs met, the desire to outwit authority figures, unconscious guilt, or a masochistic need to suffer. Frequent surgery may also be related to a somatiform disorder, particularly body dysmorphic disorder (an obsession that a body part is disfigured). More apparent reasons may include an attempt to get relief from pain and a lifestyle that has become almost exclusively medically oriented, with all of the risks entailed in such an endeavor.

Postoperative anxiety states are usually related to pain, procedures, and loss of body image. Acute pain problems are quite different from chronic pain disorders (see Chronic Pain Disorders, this chapter); the former are readily handled with adequate analgesic medication (see Chapter 5). Alterations in body image, as with amputations, ostomies, and mastectomies, often raise concerns about relationships with others.

3. Iatrogenic problems—These usually pertain to medications, complications of diagnostic and treatment procedures, and impersonal and unsympathetic staff behavior. Polypharmacy is often a factor. Patients with unsolved diagnostic problems are at higher risk. They are desirous of relief, and the quest engenders more diagnostic procedures with a higher incidence of complications. The upset patient and family may be very demanding. Excessive demands usually result from anxiety. Such behavior is best handled with calm and measured responses.

B. Intermediate Problems

1. Prolonged hospitalization—Prolonged hospitalization presents unique problems in certain hospital services, eg, burn units, orthopedic services, and tuberculosis wards. The acute problems of the severely burned patient are discussed in Chapter 37. The problems often are behavioral difficulties related to length of hospitalization and necessary procedures. For example, in burn units, pain is a major problem in addition to anxiety about procedures. Disputes with staff are common and often concern pain medication or ward privileges. Some patients regress to infantile behavior and dependency. Staff members must agree about their approach to the patient in order to ensure the smooth functioning of the unit.

Denial of illness may present in some patients. Intervention by an authority figure (eg, immediate work supervisor) may help the patient accept treatment and eventually abandon the coping mechanism of denial.

2. Depression—Mood disorders ranging from mild adjustment disorder to major depressive disorder frequently occur during prolonged hospitalizations. A key to the diagnosis of depression in the medical setting is the individual’s loss of self-esteem; they often think of themselves as worthless and are guilt ridden. Therapeutic medications (eg, corticosteroids) may be a factor. Depression can contribute to irritability and overt anger. Severe depression can lead to anorexia, which further complicates healing and metabolic balance. It is during this period that the issue of disfigurement arises—relief at survival gives way to concern about future function and appearance.

C. Recuperative Problems

1. Anxiety—Anxiety about return to the posthospital environment can cause regression to a dependent position. Complications increase, and staff forbearance again is tested. Anxiety occurring at this stage usually is handled more easily than previous behavior problems.

2. Posthospital adjustment—Adjustment difficulties after discharge are related to the severity of the deficits and the use of outpatient facilities (eg, physical therapy, rehabilitation programs, psychiatric outpatient treatment). Some patients may experience posttraumatic stress symptoms (eg, from traumatic injuries or even from necessary medical treatments). Lack of appropriate follow-up can contribute to depression in the patient, who may feel that he or she is making poor progress and may have thoughts of “giving up.” Reintegration into work, educational, and
social endeavors may be slow. Life is simply much more difficult when one is disfigured, disabled, or disenfranchised.

Clinical Findings

The symptoms that occur in these patients are similar to those discussed in previous sections of this chapter, eg, delirium, stress and adjustment disorders, anxiety, and depression. Behavior problems may include lack of cooperation, increased complaints, demands for medication, sexual approaches to nurses, threats to leave the hospital, and actual signing out against medical recommendations. The underlying personality structure of the individual is a major factor in coping styles (eg, the compulsive individual increases indecision, the hysterical individual increases dramatic behavior).

Differential Diagnosis

Delirium and dementia (including cases associated with HIV infection and drug abuse) must always be ruled out, since they often present with symptoms resembling anxiety, depression, or psychosis. Personality disorders existing prior to hospitalization often underlie the various behavior problems, but particularly the management problems.

Complications

Prolongation of hospitalization causes increased expense, deterioration of patient-staff relationships, and increased probabilities of iatrogenic and legal problems. The possibility of increasing posthospital treatment problems is enhanced.

Treatment

A. Medical

The most important consideration by far is to have one clinician in charge, a clinician whom the patient trusts and who is able to oversee multiple treatment approaches (see Somatoform Disorders, above). In acute problems, attention must be paid to metabolic imbalance, alcohol withdrawal, and previous drug use—prescribed, recreational, or over-the-counter. Adequate sleep and analgesia are important in the prevention of delirium. When absolute behavioral control is urgently needed, agents such as propofol, dexmedetomidine, opioids, and midazolam have been used.

Many clinicians are attuned to the early detection of the surgery-prone patient. Plastic and orthopedic surgeons are at particular risk. Appropriate consultations may help detect some problems and mitigate future ones.

Postsurgical anxiety states can be alleviated by personal attention from the surgeon. Anxiety is not so effectively lessened by ancillary medical personnel, whom the patient perceives as lesser authorities, until after the clinician has reassured the patient. Inappropriate use of “as needed” analgesia places an unfair burden on the nurse. “Patient-controlled analgesia” can improve pain control, decrease anxiety, and minimize side effects.

B. Psychological

Prepare the patient and family for what is to come. This includes the types of units where the patient will be quartered, the procedures that will be performed, and any disfigurements that will result from surgery. Repetition improves understanding. The nursing staff can be helpful, since patients frequently confide a lack of understanding to a nurse but are reluctant to do so to the physician.

Denial of illness is frequently a block to acceptance of treatment. This too should be handled with family members present (to help the patient face the reality of the situation) in a series of short interviews (for reinforcement). Dependency problems resulting from long hospitalization are best handled by focusing on the changes to come as the patient makes the transition to the outside world. Key figures are teachers, vocational counselors, and physical therapists. Challenges should be realistic and practical and handled in small steps.

Depression is usually related to the loss of familiar hospital supports, and the outpatient therapists and counselors help to lessen the impact of the loss. Some of the impact can be alleviated by anticipating, with the patient and family, the signal features of the common depression to help prevent the patient from assuming a permanent sick role (invalidism).

Suicide is always a concern when a patient is faced with despair. An honest, compassionate, and supportive approach will help sustain the patient during this trying period.

C. Behavioral

Prior desensitization can significantly allay anxiety about medical procedures. A “dry run” can be done to reinforce the oral description. Cooperation during acute problem periods can be enhanced by the use of appropriate reinforcers such as a favorite nurse or helpful family member. People who are positive reinforcers are even more helpful during the intermediate phases when the patient becomes resistant to the seemingly endless procedures (eg, debridement of burned areas).

Specific situations (eg, psychological dependency on the respirator) can be corrected by weaning with appropriate reinforcers (eg, watching a favorite movie on a DVD player when disconnected from the ventilator). Behavioral approaches should be used in a positive and optimistic way for maximal reinforcement.

Relaxation techniques and attentional distraction can be used to block side effects of a necessary treatment (eg, nausea in cancer chemotherapy).

D. Social

A change in environment requires adaptation. Because of the illness, admission and hospitalization may be more easily handled than discharge. Reintegration into society
can be difficult. In some cases, the family is a negative influence. A predischarge evaluation must be made to determine whether the family will be able to cope with the physical or mental changes in the patient. Working with the family while the patient is in the acute stage may presage a successful transition later on.

Development of a new social life can be facilitated by various self-help organizations (eg, the stoma club). Sharing problems with others in similar circumstances eases the return to a social life, which may be quite different from that prior to the illness.

**Prognosis**

The prognosis is good in all patients who have reversible medical and surgical conditions. It is guarded when there is serious functional loss that impairs vocational, educational, or societal possibilities—especially in the case of progressive and ultimately life-threatening illness.

---

DISEASES OF THE HYPOTHALAMUS & PITUITARY GLAND

ANTERIOR HYPOPITUITARISM

ESSENTIALS OF DIAGNOSIS

- Partial or complete deficiency of one or any combination of anterior pituitary hormones.
- **Adrenocorticotropic hormone deficiency:** reduced adrenal secretion of cortisol, testosterone, and epinephrine; aldosterone secretion remains intact.
- **Growth hormone (GH) deficiency:** short stature in children; asthenia, obesity, and increased cardiac mortality in adults.
- **Prolactin deficiency:** inhibition of postpartum lactation.
- **Thyroid-stimulating hormone (TSH) deficiency:** secondary hypothyroidism.
- **Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) deficiency:** hypogonadism and infertility in men and women.

General Considerations

Hypopituitarism can be caused by either hypothalamic or pituitary dysfunction. Patients with hypopituitarism may have single or multiple hormonal deficiencies (Table 26–1). When one hormonal deficiency is discovered, others may be present.

1. **Hypopituitarism caused by mass lesions**—Lesions in the hypothalamus, pituitary stalk, or pituitary can cause hypopituitarism. Pituitary adenomas are usually sporadic but are sometimes part of multiple endocrine neoplasia type 1 (MEN 1). Pituitary tumors that arise in MEN 1 usually secrete prolactin (63%), GH (9%), or both (10%) and are more aggressive than sporadic adenomas. Pituitary tumors rarely cause diabetes insipidus.

Other types of mass lesions include granulomas (eg, granulomatosis with polyangiitis [formerly Wegener granulomatosis], tuberculosis), Rathke cleft cysts, apoplexy, metastatic carcinomas, aneurysms, and brain tumors (craniopharyngioma, meningioma, dysgerminoma, glioma, chondrosarcoma, chordoma of the clivus). Autoimmune hypophysitis, postpartum pituitary necrosis (Sheehan syndrome), eclampsia–preeclampsia, sickle cell disease, and African trypanosomiasis are rare causes. Langerhans cell histiocytosis usually presents in youth with diabetes insipidus or hypopituitarism; osteolytic bone lesions are noted on radiographs.

2. **Hypopituitarism without mass lesions**—This may be congenital in syndromes such as septo-optic dysplasia (de Morsier syndrome). Congenital hypopituitarism also develops in patients with PROP1 and other gene mutations. Hypopituitarism may also be caused by cranial radiation, surgery, encephalitis, hemochromatosis, or autoimmunity. It may also occur after coronary artery bypass grafting. At least one pituitary hormone deficiency develops in about 25–30% of survivors of moderate to severe traumatic brain injury (Glasgow Coma Scale ≤13/15) and in about 55% of survivors of aneurysmal subarachnoid hemorrhage. Some degree of hypopituitarism occurs in one-third of ischemic stroke patients, most commonly GH deficiency and hypogonadotropic hypogonadism. Mitotane, given for adrenal cortical carcinoma, can suppress TSH secretion and cause reversible secondary hypothyroidism. Therapy with exogenous corticosteroids (parenteral, oral, inhaled, or topical) can suppress adrenocorticotropic hormone (ACTH) secretion and causes functional isolated secondary adrenal insufficiency.

Congenital isolated hypogonadotropic hypogonadism can be caused by various gene mutations that control the production or release of gonadotropin-releasing hormone (GnRH), LH, or FSH. *Congenital adrenal hypoplasia* (see below) is one cause of isolated hypogonadotropic hypogonadism. It may be autosomal recessive or X-linked; the X-linked form is caused by a mutation in the *DAX 1* gene. Adrenal insufficiency, caused by failure to form the adrenal cortex, can present during infancy or childhood in boys with *DAX 1* gene mutations. *Prader-Willi syndrome*
Acquired gonadotropin deficiency is characterized by the loss of axillary, pubic, and body hair. This occurs gradually but becomes particularly prominent in patients who are also hypoadrenal. Men may note diminished beard growth. Libido is diminished. Women have amenorrhea; men note decreased erections. Most patients are infertile. Androgen deficiency predisposes patients to osteopenia and muscle atrophy. (See sections on male hypogonadism and secondary amenorrhea.) Advancing age, obesity, and poor health also cause partial male hypogonadism. (See Male Hypogonadism.)

2. TSH deficiency—TSH deficiency causes hypothyroidism with manifestations such as fatigue, weakness, weight change, and hyperlipidemia. Bexarotene is a retinoid chemotherapeutic agent that suppresses TSH secretion and circulating levels of T4 and T3, thereby inducing reversible secondary hypothyroidism. (See Hypothyroidism and Myxedema.)

3. ACTH deficiency—This results in diminished cortisol secretion (see Adrenocortical Hypofunction). Symptoms may include weakness, fatigue, weight loss, and hypotension. Patients with partial ACTH deficiency continue to have some cortisol secretion and may not have symptoms until stressed by illness or surgery. Adrenal mineralocorticoid secretion continues, so manifestations of adrenal insufficiency in hypopituitarism are usually less striking than in bilateral adrenal gland destruction (Addison disease); hyponatremia may occur, especially when ACTH and TSH deficiencies are both present.

4. GH deficiency—When GH deficiency is congenital, it presents with hypoglycemia in infancy and short stature in childhood. GH deficiency in adulthood tends to cause mild to moderate central obesity, increased systolic blood pressure, increased low-density lipoprotein (LDL) cholesterol, and reduced cardiac output. Affected patients may also have reduced muscle and bone mass, reduced physical and mental energy, impaired concentration and memory, and depression. Laron syndrome is an autosomal recessive disorder that is mainly associated with mutations in GH receptor gene. This causes resistance to GH and severe insulin-like growth factor-I (IGF-I) deficiency, resulting in short stature (dwarfism). Affected individuals have a prominent forehead, depressed nasal bridge, small mandible, and central obesity. They may have recurrent hypoglycemic seizures. Partial resistance to GH may cause some cases of idiopathic short stature without features of Laron syndrome.

5. Combined pituitary hormone deficiency and panhypopituitarism—The conditions refer to a deficiency of several or all pituitary hormones. Combined pituitary hormone deficiency gradually develops in patients with PROP 1 gene mutations, usually presenting with short stature and growth failure due to GH and TSH deficiency; lack of pubertal development occurs due to deficiencies in FSH and LH. ACTH-cortisol deficiency also gradually develops in patients with PROP 1 gene mutations; these patients typically require corticosteroid replacement therapy by age 18 years. In addition to the

### Clinical Findings

#### A. Symptoms and Signs

1. Gonadotropin deficiency—Also known as hypogonadotropic hypogonadism, gonadotropin deficiency is caused by insufficiencies in LH and FSH, which cause hypogonadism and infertility. Congenital gonadotropin deficiency is characterized by partial or complete lack of pubertal development. (See discussion of primary amenorrhea.) Patients with Kallmann syndrome have hypogonadism and anosmia or hyposmia. Half of these patients have unilateral renal agenesis. Some patients with Kallmann syndrome may also exhibit cryptorchidism, micropenis, color blindness, sensorineural deafness, cerebellar ataxia, cognitive problems, bimanual synkinesis, cleft lip or palate, or high-arched palate. Some affected women have menarche followed by secondary amenorrhea.

Patients with congenital adrenal hypoplasia have congenital normosmic idiopathic hypogonadotropic hypogonadism. Boys with congenital adrenal hypoplasia who survive beyond childhood usually do not enter puberty as a result of their hypogonadotropic hypogonadism. However, hypogonadotropic hypogonadism and subtle signs of adrenal failure can present in adulthood in males with partial loss-of-function mutations in DAX 1. Patients with Prader-Willi syndrome have variable features of both gonadotropin deficiency and primary gonadal dysfunction; boys have cryptorchidism. Other features of Prader-Willi syndrome can include mental retardation, short stature, hyperflexibility, autonomic dysregulation, cognitive impairment, and hyperphagia with obesity.
manifestations noted above, patients with long-standing hypopituitarism tend to have dry, pale, finely textured skin. The face has fine wrinkles and an apathetic countenance.

6. Other manifestations—Hypothalamic damage can cause obesity and cognitive impairment. Local tumor effects can cause headache or optic nerve compression with visual field impairment.

B. Laboratory Findings

The fasting blood glucose may be low. Hyponatremia is often present due to hypothroidism or hypoadrenalism. Hyperkalemia usually does not occur, since aldosterone production is not affected.

For men, an accurate serum total testosterone measurement must be obtained. For older men, free testosterone is best measured by calculation, using accurate assays for testosterone and sex hormone binding globulin. Serum gonadotropins (FSH and LH) are obtained if the serum testosterone is low in order to distinguish primary hypogonadism from pituitary dysfunction.

The free thyroxine (FT₄) level is low, and TSH is usually not elevated. However, hypothyroidism with a paradoxically increased serum TSH has been reported in some patients with hypothalamic hypopituitarism. Plasma levels of sex steroids (testosterone and estradiol) are low or low normal, as are the serum gonadotropins. Elevated prolactin (PRL) levels are found in patients with prolactinomas, acromegaly, and hypothalamic disease.

ACTH deficiency usually causes functional atrophy of the adrenal cortex within 2 weeks of pituitary destruction. Therefore, the diagnosis of secondary hypoadrenalism can usually be confirmed with cosyntropin testing. For the cosyntropin test, patients should be either taking no corticosteroids or a short-acting corticosteroid (such as hydrocortisone), which is held after midnight on the morning of the test. At 8 AM, blood is drawn for serum cortisol, ACTH, and dehydroepiandrosterone (DHEA); then 0.25 mg of cosyntropin (synthetic ACTH1–24) is administered intramuscularly or intravenously. Another blood sample is obtained 45 minutes after the cosyntropin administration to remeasure serum cortisol levels. A stimulated serum cortisol of < 20 mcg/dL (550 nmol/mL) indicates adrenal insufficiency. With gradual pituitary damage and early in the course of ACTH deficiency, patients can have a stimulated serum cortisol of ≥ 20 mcg/dL but a baseline 8 AM serum cortisol < 5 mcg/dL (137.5 nmol/L), which is suspicious for adrenal insufficiency. Serum DHEA levels are usually low in patients with adrenal deficiency, helping confirm the diagnosis. A baseline ACTH level is low or normal in secondary hypoadrenalism, distinguishing it from primary adrenal disease. For patients with symptoms of secondary adrenal insufficiency (hypotension, hypotension, pituitary tumor) but borderline cosyntropin testing, treatment can be instituted empirically. The cosyntropin test may be repeated at a later date. Insulin tolerance testing and metyrapone testing are usually unnecessary.

Deficiency of epinephrine occurs with secondary adrenal insufficiency, since high local concentrations of cortisol are required to induce the production of the enzyme phenylethanolamine N-methyltransferase (PNMT) in the adrenal medulla that catalyzes the conversion of norepinephrine to epinephrine.

The diagnosis of GH deficiency is difficult since normal GH secretion is pulsatile and serum GH levels are nearly undetectable for most of the day. Also, adults normally tend to produce less GH as they age. Therefore, GH deficiency is often inferred by symptoms of GH deficiency in the presence of pituitary destruction or other pituitary hormone deficiencies. GH deficiency is present in 96% of patients with three or more other pituitary hormone deficiencies. GH stimulates the production of IGF-I. Unfortunately, serum IGF-I is not sensitive for GH deficiency since IGF-I levels are in the normal range in about 50% of adults with GH deficiency. Low serum IGF-I levels are not specific for GH deficiency; however, a very low level of IGF-I (< 84 mcg/L) is indicative of GH deficiency, except in conditions that naturally suppress serum IGF-I (eg, malnutrition, prolonged fasting, oral estrogen, hypothyroidism, uncontrolled diabetes mellitus, liver failure). In GH deficiency, exercise-stimulated serum GH levels remain < 5 ng/mL and usually fail to rise; however, by age 40 years, most normal adults have lost their GH response to exercise.

Provocative GH-stimulation tests are commonly used but are poor tests for GH deficiency. The insulin hypoglycemia test is now rarely used. Other GH stimulation tests require the administration of intravenous arginine and growth hormone–releasing hormone (GHRH) and oral clonidine or carbidopa/levodopa (combination) in patients pretreated with propranolol or estrogen. However, these tests do not discriminate well between normal individuals and patients with presumed GH deficiency (patients with three or more other pituitary hormone deficiencies). Also, normal overweight adults (body mass index [BMI] ≥ 25 kg/m²) typically have blunted peak GH levels after arginine-GHRH administration.

Despite the limitations of intravenous GHRH/arginine stimulation testing, some insurance companies insist that patients have an abnormal test before covering the costs of GH replacement therapy. However, the latter test has a sensitivity of only 66% for GH deficiency. Therefore, when patients have a serum IGF-I < 84 mcg/L or three other pituitary hormone deficiencies, the likelihood of GH deficiency is so high that symptomatic patients should have a therapeutic trial of GH therapy.

The differential diagnosis of GH deficiency is congenital GH resistance with deficiency of IGF-I; at its worst, IGF-I deficiency results in Laron dwarfism that is resistant to GH therapy.

Patients with hypopituitarism without an established etiology should be screened for hemochromatosis with a serum iron and transferrin saturation or ferritin since hemochromatosis can cause hypopituitarism.

C. Imaging

MRI provides the best visualization of pituitary and hypothalamic tumors. Thickening of the pituitary stalk can be caused by sarcoidosis or hypophysitis.
Differential Diagnosis
The failure to enter puberty may simply reflect delayed puberty, also known as constitutional delay in growth and puberty. Reversible hypogonadotropic hypogonadism may occur with serious illness, malnutrition, anorexia nervosa, or morbid obesity. Men typically develop partial secondary hypogonadism with aging. The clinical situation and the presence of normal adrenal and thyroid function allow ready distinction from hypopituitarism. Profound hypogonadotropic hypogonadism develops in men who receive GnRH analog therapy (leuprolide) for prostate cancer; it usually persists following cessation of therapy. Hypogonadotropic hypogonadism usually develops in patients receiving opioid therapy, including high-dose methadone or long-term intrathecal infusion of opioids; both GH deficiency and secondary adrenal insufficiency occur in 15% of such patients. Secondary adrenal insufficiency may persist for many months following high-dose corticosteroid therapy.

Severe illness causes functional suppression of TSH and T<sub>4</sub>. Hyperthyroxinemia reversibly suppresses TSH. Administration of triiodothyronine (Cytomel) suppresses TSH and T<sub>3</sub>. Bexarotene, used to treat cutaneous T cell lymphoma, suppresses TSH secretion, resulting in temporary central hypothyroidism. Corticosteroids or megestrol treatment reversibly suppresses endogenous ACTH and cortisol secretion.

GH deficiency normally occurs with aging. Physiologic GH deficiency that develops in obese patients may return to normal with sufficient weight loss.

Complications
Among patients with craniopharyngiomas, diabetes insipidus is found in 16% preoperatively and in 60% postoperatively. Hyponatremia often presents abruptly during the first 2 weeks following pituitary surgery. Visual field impairment may occur. Hypothalamic damage may result in morbid obesity as well as cognitive and emotional problems. Conventional radiation therapy results in an increased incidence of small vessel ischemic strokes and second tumors.

Patients with untreated hypoadrenalism and a stressful illness may become febrile and die in shock and coma. Adults with GH deficiency have experienced an increased cardiovascular morbidity. Rarely, acute hemorrhage may occur in large pituitary tumors, manifested by rapid loss of vision, headache, and evidence of acute pituitary failure (pituitary apoplexy) requiring emergency decompression of the sella.

Treatment
Transphenoidal removal of pituitary tumors will sometimes reverse hypopituitarism. Postoperative hyponatremia often occurs; serum sodium must be checked frequently for 2 weeks after pituitary surgery. Hypogonadism due to PRL excess usually resolves during treatment with dopamine agonists. Endocrine substitution therapy must be given before, during and, often, permanently after such procedures.

GH-secreting tumors may respond to octreotide (see section on acromegaly). Radiation therapy with x-ray, gamma knife, or heavy particles may be necessary but increases the likelihood of hypopituitarism.

The mainstay of substitution therapy for pituitary insufficiency remains lifetime hormone replacement.

A. Corticosteroids
Hydrocortisone tablets, 15–35 mg/d orally in divided doses, should be given. Most patients do well with 10–20 mg in the morning and 5–15 mg in the late afternoon. Patients with partial ACTH deficiency (basal morning serum cortisol above 8 mg/dL [220 mmol/L]) require hydrocortisone replacement in lower doses of about 5 mg orally twice daily. Some patients feel better taking prednisone, 3–7.5 mg/d orally. A mineralocorticoid is rarely needed. To determine the optimal corticosteroid replacement dosage, it is necessary to monitor patients carefully for manifestations of overreplacement (Cushing syndrome) or underreplacement. A serum white blood cell count (WBC) with a relative differential can be useful, since a relative neutrophilia and lymphopenia can indicate overreplacement with corticosteroid, and vice versa. Additional corticosteroids must be given during states of stress, eg, during infection, trauma, or surgical procedures. For mild illness, corticosteroid doses are doubled or tripled. For trauma or surgical stress, hydrocortisone is given in doses of 50 mg intramuscularly or intravenously every 6 hours and then reduced to normal doses as the stress subsides. Patients with adrenal insufficiency are advised to wear a medical alert bracelet describing their condition and treatment.

Patients with secondary adrenal insufficiency due to treatment with corticosteroids at supraphysiologic doses require their usual daily dose of corticosteroid during surgery and acute illness; supplemental hydrocortisone is not usually required.

B. Thyroid
Levothyroxine is given to correct hypothyroidism only after the patient is assessed for cortisol deficiency or is already receiving corticosteroids. (See Hypothyroidism.) The typical maintenance dose is about 1.6 mcg/kg body weight. However, dosage requirements vary widely, averaging 125 mcg daily with a range of 25–300 mcg daily. The optimal replacement dose of thyroxine for each patient must be carefully assessed clinically on an individual basis. Serum FT<sub>4</sub> levels usually need to be in the high-normal range for adequate replacement. Assessment of serum TSH is useless for monitoring patients, since levels are always low with TSH deficiency.

C. Sex Hormones
Hypogonadotropic hypogonadism often develops in patients with hyperprolactinemia; it may be reversed with treatment of the hyperprolactinemia. (See Hyperprolactinemia.) Androgen replacement is discussed in the section on male hypogonadism. Estrogen replacement is discussed in the section on female hypogonadism. Patients with idiopathic hypogonadotropic hypogonadism, who have received several years of hormone replacement therapy
(HRT), may have a trial off hormonal therapy to assess whether spontaneous sexual maturation may have occurred.

Women with hypopituitarism and secondary adrenal insufficiency whose serum DHEA levels are < 400 ng/mL may be treated with compounded DHEA in doses of about 25–50 mg/d orally. DHEA therapy tends to increase pubic and axillary hair and may modestly improve libido, alertness, stamina, and overall psychological well being after 6 months of therapy.

To improve spermatogenesis, human chorionic gonadotropin (hCG) (equivalent to LH) may be given at a dosage of 2000–3000 units intramuscularly three times weekly and testosterone replacement is discontinued. The dose of hCG is adjusted to normalize serum testosterone levels. After 6–12 months of hCG treatment, if the sperm count remains low, hCG injections are continued along with injections of FSH: follitropin-β (synthetic recombinant FSH) or urofollitropins (urine-derived FSH). An alternative for patients with an intact pituitary (eg, Kallmann syndrome) is the use of leuprolide (GnRH analog) by intermittent subcutaneous infusion. With either treatment, testicular volumes double within 5–12 months, and spermatogenesis occurs in most cases. With persistent treatment and the help of intracytoplasmic sperm injection for some cases, the total pregnancy success rate is about 70%. Clomiphene, 25–50 mg orally daily, can sometimes stimulate a man’s own pituitary gonadotropins (when his pituitary is intact), thereby increasing testosterone and sperm production.

For fertility induction in females, ovulation may be induced with clomiphene, 50 mg daily for 5 days every 2 months. Follitropins and hCG can induce multiple births and should be used only by those experienced with their administration. (See Hypogonadism.)

**D. Human Growth Hormone (hGH)**

Symptomatic adults with severe GH deficiency (serum IGF-I < 85 mcg/L) may be treated with a subcutaneous recombinant human growth hormone (rhGH) injection starting at a dosage of about 0.2 mg/d (0.6 international units/d), administered three or four times weekly. The dosage of rhGH is increased every 2–4 weeks by increments of 0.1 mg (0.3 international units) until side effects occur or a sufficient salutary response and a normal serum IGF-I level are achieved. A sustained-release injectable suspension of depot GH is available (Nutropin Depot). It can be given twice monthly and is therefore more convenient than standard rhGH preparations. In a study of 20 Brazilian GH-deficient adults, depot GH, given in doses of 13.5 mg subcutaneously twice monthly over 6 months, improved body morphology and lipid profiles but was associated with an increase in carotid plaque. If the desired effects (eg, improved energy and mentation, reduction in visceral adiposity) are not seen within 3–6 months at maximum tolerated dosage, rhGH therapy is discontinued.

During pregnancy, rhGH may be safely administered to women with hypopituitarism at their usual pregestational dose during the first trimester, tapering the dose during the second trimester, and discontinuing rhGH during the third trimester.

Oral estrogen replacement reduces hepatic IGF-I production. Therefore, prior to commencing rhGH therapy, oral estrogen is changed to a transdermal or transvaginal estradiol.

Side effects of rhGH therapy may include peripheral edema, hand stiffness, arthralgias, myalgias, headache, pseudotumor cerebri, gynecomastia, carpal tunnel syndrome, tarsal tunnel syndrome, hypertension, and proliferative retinopathy. Side effects are more common in older patients, those with greater weight and higher BMI, and those with adult-onset GH deficiency. Such symptoms usually remit promptly after a sufficient reduction in dosage. Excessive doses of rhGH could cause acromegaly; patients receiving long-term therapy require careful clinical monitoring. Serum IGF-I levels should be kept in the normal range and periodic determinations of serum IGF-I levels are helpful in guiding therapeutic dosing.

GH should not be administered during critical illness since, in one study, administration of very high doses of rhGH to patients in an intensive care unit was shown to increase overall mortality. There is no role for GH replacement in the somatopause of aging.

IGF-I (meascarmin) is available to treat patients with Laron syndrome.

**E. Other Treatment**

Selective transphenoidal resection of pituitary adenomas can often restore normal pituitary function. Cabergoline, bromocriptine, or quinagolide may reverse the hypogonadism seen in hyperprolactinemia. (See Disorders of Prolactin Secretion.) Disseminated Langerhans cell histiocytosis may be treated with bisphosphonates to improve bone pain; treatment with 2-chlorodeoxyadenosine (cladribine) has been reported to produce remissions.

**Prognosis**

The prognosis depends on the primary cause. Hypopituitarism resulting from a pituitary tumor may be reversible with dopamine agonists or with careful selective resection of the tumor. Spontaneous recovery from hypopituitarism associated with pituitary stalk thickening has been reported. Patients can also recover from functional hypopituitarism, eg, hypogonadism due to starvation or severe illness, suppression of ACTH by corticosteroids, or suppression of TSH by hyperthyroidism. Spontaneous reversal of isolated idiopathic hypogonadotropic hypogonadism occurs in about 10% of patients after several years of hormone replacement therapy.

Functionally, most patients with hypopituitarism do very well with hormone replacement. Men with infertility who are treated with hCG/FSH or GnRH are likely to resume spermatogenesis if they have a history of sexual maturation, descended testicles, and a baseline serum inhibin level over 60 pg/mL. Women under age 40 years, with infertility due to hypogonadotropic hypogonadism, can usually have successful induction of ovulation.

DIABETES INSIPIDUS

ESSENTIALS OF DIAGNOSIS

- Antidiuretic hormone (ADH) deficiency causes central diabetes insipidus with polyuria (2–20 L/d) and polydipsia.
- Hyponatremia occurs if fluid intake is inadequate.
- General Considerations

Diabetes insipidus is an uncommon disease characterized by an increase in thirst and the passage of large quantities of urine of low specific gravity (usually < 1.006 with ad libitum fluid intake). The urine is otherwise normal. It is caused by a deficiency of vasopressin or resistance to vasopressin.

Primary central diabetes insipidus (without an identifiable lesion noted on MRI of the pituitary and hypothalamus) accounts for about one-third of all cases of diabetes insipidus. Many such cases appear to be due to autoimmunity against hypothalamic arginine vasopressin (AVP)-secreting cells; pituitary stalk thickening can often be detected on pituitary MRI scanning. The cause may also be genetic. Familial diabetes insipidus occurs as a dominant genetic trait with symptoms developing at about 2 years of age. Diabetes insipidus also occurs in Wolfram syndrome, a rare autosomal recessive disorder that is also known by the acronym DIDMOAD (diabetes insipidus, type I diabetes mellitus, optic atrophy, and deafness). DIDMOAD manifestations usually present in childhood but may not occur until adulthood, along with depression and cognitive problems. Diabetes insipidus can also occur in the preleukemic phase of acute myelogenous leukemia associated with myelodysplasia. Secondary central diabetes insipidus is due to damage to the hypothalamus or pituitary stalk by tumor, hypophysitis, anoxia encephalopathy, surgical or accidental trauma, infection (eg, encephalitis, tuberculosis, syphilis), sarcoidosis, or multifocal Langerhans cell (eosinophilic) granulomatosis (“histiocytosis X”). Metastases to the pituitary are more likely to cause diabetes insipidus (33%) than are pituitary adenomas (1%).

Vasopressinase-induced diabetes insipidus may be seen in the last trimester of pregnancy and in the puerperium. A circulating enzyme destroys native vasopressin; however, synthetic desmopressin is unaffected. Nephrogenic diabetes insipidus is a disorder caused by a defect in the kidney tubules that interferes with water reabsorption. These patients have normal secretion of vasopressin, and the polyuria is unresponsive to it. Congenital nephrogenic diabetes insipidus is present from birth and is due to defective expression of renal vasopressin V2 receptors or vasopressin-sensitive water channels. It occurs as a familial X-linked trait; adults often have hyperuricemia as well. Acquired forms of vasopressin-resistant diabetes insipidus are usually less severe and are seen in pyelonephritis, renal amyloidosis, myeloma, potassium depletion, Sjögren syndrome, sickle cell anemia, or chronic hypercalcemia. The disorder may occur also as a corticosteroid effect or as an acute side effect of diuretics. Certain drugs (eg, demeclocycline, lithium, foscarin, or mexitilin) may induce nephrogenic diabetes insipidus. The recovery from acute tubular necrosis may also be associated with transient nephrogenic diabetes insipidus. (See Kidney Disorders.)

Clinical Findings

A. Symptoms and Signs

The symptoms of the disease are intense thirst, especially with a craving for ice water, and polyuria, the volume of ingested fluid varying from 2 L to 20 L daily, with correspondingly large urine volumes. Partial diabetes insipidus presents with less intense symptoms and should be suspected in patients with unremitting enuresis. Most patients with diabetes insipidus are able to maintain fluid balance by continuing to ingest large volumes of water. However, diabetes insipidus may present with hypernatremia and dehydration in patients without free access to water, or with a damaged hypothalamic thirst center and altered thirst sensation. Diabetes insipidus is aggravated by administration of high-dose corticosteroids, which increases renal free water clearance. Vasopressin-induced diabetes insipidus during pregnancy is often associated with oligohydramnios, preeclampsia, or hepatic dysfunction.

B. Laboratory Findings

The diagnosis of diabetes insipidus as a cause of polyuria or hypernatremia requires clinical judgment. There is no
single diagnostic laboratory test. Evaluation for diabetes insipidus should include an accurate 24-hour urine collection that is measured for volume and creatinine. A urine volume of <2 L/24 h (in the absence of hypernatremia) essentially rules out diabetes insipidus. Serum is assayed for glucose, urea nitrogen, calcium, potassium, sodium, and uric acid. Hyperuricemia occurs in many patients with diabetes insipidus, since reduced vasopressin stimulation of the renal V1 receptor causes a reduction in the renal tubular clearance of urate.

A supervised “vasopressin challenge test” may be given: Desmopressin acetate is given in an initial dose of 0.05–0.1 mL (5–10 mcg) intranasally (or 1 mcg subcutaneously or intravenously), with measurement of urine volume for 12 hours before and 12 hours after administration. Serum sodium must be obtained immediately in the event of symptoms of hyponatremia. The dosage of desmopressin is doubled if the response is marginal. Patients with central diabetes insipidus notice a distinct reduction in thirst and polyuria; serum sodium stays normal except in some salt-losing conditions.

In nonfamilial central diabetes insipidus, MRI of the pituitary and hypothalamus and of the skull is done to look for mass lesions. The pituitary stalk may be thickened, which may be a manifestation of Langerhans cell histiocytosis, sarcoidosis, or lymphocytic hypophysitis. When nephrogenic diabetes insipidus is a diagnostic consideration, measurement of serum vasopressin is done during modest fluid restriction; typically, the vasopressin level is high.

Differential Diagnosis
Central diabetes insipidus must be distinguished from polyuria caused by psychogenic polydipsia, diabetes mellitus, Cushing syndrome or corticosteroid treatment, lithium, hypercalcaemia, hypokalaemia, and the nocturnal polyuria of Parkinson disease. It must also be distinguished from vasopressinase-induced diabetes insipidus and nephrogenic diabetes insipidus.

Complications
If water is not readily available, the excessive output of urine will lead to severe dehydration. Patients with an impaired thirst mechanism are very prone to hypernatremia, particularly since they usually also have impaired mentation and forget to take their desmopressin. All the complications of the primary disease may eventually become evident. In patients who are receiving desmopressin acetate therapy, there is a danger of induced water intoxication.

Treatment
Mild cases of diabetes insipidus require no treatment other than adequate fluid intake. Reduction of aggravating factors (eg, corticosteroids, which directly increase renal free water clearance) will improve polyuria.

Desmopressin acetate is the treatment of choice for central diabetes insipidus. It is also useful in diabetes insipidus associated with pregnancy or the puerperium, since desmopressin is resistant to degradation by the circulating vasopressinase.
ACROMEGALY & GIGANTISM

ESSENTIALS OF DIAGNOSIS

► Pituitary tumor.
► Excessive growth of hands, feet, jaw, and internal organs; or gigantism before closure of epiphyses.
► Amenorrhea, headaches, visual field loss, weakness.
► Soft, doughy, sweaty handshake.
► Elevated serum GH not suppressed following oral glucose.

General Considerations

GH exerts much of its growth-promoting effects by stimulating the release of IGF-I from the liver and other tissues. Acromegaly is nearly always caused by a pituitary adenoma. These tumors may be locally invasive, particularly into the cavernous sinus. Less than 1% are malignant. Most are macroadenomas (over 1 cm in diameter). Acromegaly is usually sporadic but may rarely be familial. The disease may also be associated with endocrine tumors of the parathyroids or pancreas (MEN 1). Acromegaly may also be seen in McCune-Albright syndrome and as part of Carney syndrome (atrial myxoma, acoustic neuroma, lentigines, adrenal hypercortisolism). Acromegaly is rarely caused by ectopic secretion of GHRH or GH secreted by a lymphoma, hypothalamic tumor, bronchial carcinoid, or pancreatic tumor.

Clinical Findings

A. Symptoms and Signs

Excessive GH causes tall stature and gigantism if it occurs in youth, before closure of epiphyses. Afterward, acromegaly develops. The term “acromegaly,” meaning extremity enlargement, seriously underestimates the manifestations. The hands enlarge and a doughy, moist handshake is characteristic. The fingers widen, causing patients to enlarge their rings. Carpal tunnel syndrome is common. The feet also grow, particularly in shoe width. Facial features coarsen since the bones and sinuses of the skull enlarge; hat size increases. The mandible becomes more prominent, causing proptosis and malocclusion. Tooth spacing widens. Older photographs of the patient can be a useful comparison.

Macroglossia occurs, as does hypertrophy of pharyngeal and laryngeal tissue; this causes a deep, coarse voice and sometimes makes intubation difficult. Obstructive sleep apnea may occur. A goiter may be noted. Hypertension (50%) and cardiomegaly are common. At diagnosis, about 10% of acromegalic patients have overt heart failure, with a dilated left ventricle and a reduced ejection fraction. Weight gain is typical, particularly of muscle and bone. Insulin resistance is usually present and frequently causes diabetes mellitus (30%). Arthralgias and degenerative arthritis occur. Overgrowth of vertebral bone can cause spinal stenosis. Colon polyps are common, especially in patients with skin papillomas. The skin may also manifest hyperhidrosis, thickening, cystic acne, skin tags, and areas of acanthosis nigricans.

GH-secreting pituitary tumors usually cause some degree of hypogonadism, either by cosecretion of PRL or by direct pressure upon normal pituitary tissue. Decreased libido and erectile dysfunction are common. Women with acromegaly may experience irregular menses or amenorrhea; those who become pregnant have an increased risk of gestational diabetes and hypertension. Secondary hypothyroidism sometimes occurs; hypoadrenalism is unusual. Headaches are frequent. Temporal hemianopia may occur as a result of the optic chiasm being impinged by a suprasellar growth of the tumor.

B. Laboratory Findings

For screening purposes, a random serum IGF-I can be obtained. If it is normal for age, acromegaly is ruled out. For further evaluation, the patient should be fasting for at least 8 hours (except for water), not acutely ill, and should not have exercised on the day of testing. Assay for the following: IGF-I (increased over five times normal in most acromegalic patients), PRL (cosecreted by many GH-secreting tumors), glucose (diabetes is common in acromegaly), liver enzymes and blood urea nitrogen (BUN) (liver failure or kidney disease can misleadingly elevate GH), serum calcium (to screen for hyperparathyroidism), serum inorganic phosphorus (frequently elevated), serum free T₄ and TSH (secondary hypothyroidism is common in acromegaly; primary hypothyroidism may increase PRL; hyperthyroidism may occur as a result of excess TSH).

Glucose syrup (75 g) is then administered orally, and serum GH is measured 60 minutes afterward; acromegaly is excluded if the serum GH is < 1 ng/mL (immunoradiometric assay [IRMA] or chemiluminescent assays). For ultrasensitive GH assays, GH should be suppressed to < 0.3 ng/mL to exclude acromegaly. The serum IGF-I and glucose-suppressed GH are usually complementary tests; however, disparities between GH and IGF-I levels occur in up to 30% of patients.

C. Imaging

MRI shows a pituitary tumor in 90% of acromegalic patients. These tumors ordinarily involve the sella and cavernous sinus; rare ectopic tumors may arise in the sphenoid bone. MRI is generally superior to CT scanning, especially in the postoperative setting. Radiographs of the skull may show an enlarged sella and thickened skull. Radiographs may also show tufting of the terminal phalanges of the fingers and toes. A lateral view of the foot shows increased thickness of the heel pad.

Differential Diagnosis

Active acromegaly must be distinguished from familial coarse features, large hands and feet, and isolated prog-nathism and from inactive (“burned-out”) acromegaly in which there has been a spontaneous remission due to infarction of the pituitary adenoma. GH-induced gigantism...
must be differentiated from familial tall stature and from aromatase deficiency. (See Osteoporosis.)

Misleadingly high serum GH levels can be caused by exercise or eating just prior to the test; acute illness or agitation; liver failure or kidney disease; malnourishment; diabetes mellitus; or concurrent treatment with estrogens, β-blockers, or clonidine. During normal adolescence, serum IGF-I is usually elevated and GH may fail to be suppressed.

Complications

Complications include hypopituitarism, hypertension, glucose intolerance or frank diabetes mellitus, cardiac enlargement, and cardiac failure. Carpal tunnel syndrome may cause thumb weakness and thenar atrophy; Arthritis of hips, knees, and spine can be troublesome. Cord compression may be seen. Visual field defects may be severe and progressive. Acute loss of vision or cranial nerve palsy may occur if the tumor undergoes spontaneous hemorrhage and necrosis (pituitary apoplexy). Colon polyps are more likely to develop in patients with acromegaly.

Treatment

Pituitary microsurgery is the treatment of choice for patients with acromegaly. Many patients have an apparent surgical cure and a remission in all clinical symptoms but continue to have a mildly elevated serum GH or IGF-I postoperatively. If no residual tumor is apparent on MRI, the patient may elect to be monitored closely, rather than embark on adjuvant medical therapy that is expensive and carries its own risks (see below).

A. Pituitary Microsurgery

Endoscopic transnasal, transphenoidal pituitary microsurgery removes the adenoma while preserving anterior pituitary function in most patients. Surgical remission is achieved in about 70% of patients followed over 3 years. GH levels fall immediately; diaphoresis and carpal tunnel syndrome often improve within a day after surgery. Transphenoidal surgery is usually well tolerated, but complications occur in about 10% of patients, including infection, cerebrospinal fluid leak, and hypopituitarism. Transphenoidal pituitary surgery may be difficult in patients with McCune–Albright syndrome because of fibrous dysplasia of the skull base.

Fluid and electrolyte disturbances occur in most patients postoperatively. Diabetes insipidus can occur within 2 days postoperatively but is usually mild and self-correcting. Hyponatremia can occur abruptly 4–13 days postoperatively in 21% of patients; symptoms may include nausea, vomiting, headache, malaise, or seizure. It is treated with fluid restriction and salt supplements. It is prudent to monitor serum sodium levels postoperatively. Dietary salt supplements for 2 weeks postoperatively may help prevent this complication.

Corticosteroids are administered perioperatively and tapered to replacement doses over 1 week; hydrocortisone is discontinued and cosyntropin stimulation test is performed about 6 weeks after surgery. At that time, a serum T₄ can be checked (to screen for secondary hypothyroidism) and the patient is screened for secondary hypogonadism (see above).

B. Medications

Patients who do not have a clinical or biochemical remission after surgery may be treated with a dopamine agonist (eg, cabergoline), somatostatin analogs, pegvisomant, or a combination of these medications. Cabergoline may be used first, since it is an oral medication. Cabergoline therapy is most successful for tumors that secrete both PRL and GH but can also be effective for patients with normal serum PRL levels. Therapy with cabergoline will shrink one-third of such tumors by more than 50%. The initial dose is 0.25 mg orally twice weekly, which is gradually increased to a maximum dosage of 1 mg twice weekly, if tolerated by the patient based on serum GH and IGF-I levels. Side effects of cabergoline include nausea, fatigue, constipation, abdominal pain, and dizziness. Long-term therapy with dopamine agonists (cabergoline, bromocriptine, or pergolide) for pituitary tumors has not caused the cardiac valve problems that can occur when much higher doses are used for Parkinson disease.

Octreotide and lanreotide are somatostatin analogs that are given by subcutaneous injection. Octreotide (Sandostatin LAR depot) is given at a dose of 20–40 mg intraglutecally monthly. Lanreotide acetate (Somatuline Depot) is given by subcutaneous intraglutecal injection at a dosage of 60–120 mg monthly. Whichever preparation is used, the dosage can be adjusted to achieve serum GH levels under 2 ng/mL. Such long-acting somatostatin analogs can achieve serum GH levels under 2 ng/mL in 79% of patients and normal serum IGF-I levels in 53% of patients. Headaches often improve, and tumor shrinkage of about 30% may be expected. Acromegalic patients with pretreatment serum GH levels exceeding 20 ng/mL are less likely to respond to octreotide or lanreotide therapy. Side effects are experienced by about one-third of patients and include injection site pain, loose acholic stools, abdominal discomfort, or cholelithiasis. All somatostatin analogs are expensive and must be continued indefinitely or until other treatment has been effective.

Pegvisomant is a GH receptor antagonist that blocks hepatic IGF-I production. Pegvisomant therapy produces symptomatic relief and normalizes serum IGF-I levels in over 90% of patients. The starting dosage is 10 mg subcutaneously daily. The maintenance dosage can be increased by 5–10 mg every 4–6 weeks, based on serum IGF-I levels and liver transaminase levels; the maximum dosage is 40 mg subcutaneously daily. Pegvisomant does not shrink GH-secreting tumors. Patients need to be monitored carefully with visual field examinations, GH levels, and MRI scanning of the pituitary. Side effects of pegvisomant, including hepatitis and liver injury, have occurred in a patient with Gilbert syndrome. Other adverse effects include edema, flu-like syndrome, nausea, and hypertension. Lipohypertrophy can occur at injection sites, so the injection sites must be diligently rotated and inspected. In acromegalic diabetics, hypoglycemic drugs are reduced to avoid hypoglycemia during pegvisomant therapy. The effectiveness of pegvisomant is reduced by coadministration of opioids. Pegvisomant is detected in some GH assays, which could overestimate serum GH levels. Pegvisomant is extremely expensive.
C. Stereotactic Radiosurgery

Acromegalic patients who have not had a complete remission with transphenoidal surgery or medical therapy may be treated with **sterotactic radiosurgery** administered by gamma knife, heavy particle radiation, or adapted linear accelerator. Gamma knife radiosurgery is preferred, since it has become more widely available and normalization of serum IGF-I has been reported in up to 80% of treated patients. Radiosurgery precisely radiates the pituitary tumor in a single session and reduces radiation to the normal brain. However, it cannot be used for pituitary tumors with suprasellar extension due to the risk of damaging the optic chiasm. Radiosurgery can be used for pituitary tumors invading the cavernous sinus, since cranial nerves III, IV, V, and VI are less susceptible to radiation damage. Radiosurgery can also be used for patients who have not responded to conventional radiation therapy. Following any pituitary radiation therapy, patients are advised to take lifelong daily low-dose aspirin because of the increased risk of small-vessel stroke.

Prognosis

Patients with acromegaly have increased morbidity and mortality from cardiovascular disorders and progressive acromegalic symptoms. Those who are treated and have a random serum GH under 1.0 ng/mL or a glucose-suppressed serum GH under 0.4 ng/mL with a normal age-adjusted serum IGF-I level have reduced morbidity and mortality. Transphenoidal pituitary surgery is successful in 80% of patients with tumors < 2 cm in diameter and GH levels < 50 ng/mL. Extrasellar extension of the pituitary tumor, particularly cavernous sinus invasion, reduces the likelihood of surgical cure.

Adjuvant medical therapy has been quite successful in treating patients who are not cured by pituitary surgery. Postoperatively, normal pituitary function is usually preserved. Soft tissue swelling regresses but bone enlargement is permanent. Hypertension frequently persists despite successful surgery. Conventional radiation therapy (alone) produces a remission in about 40% of patients by 2 years and 75% of patients by 5 years after treatment. Gamma knife or cyberknife radiosurgery reduces GH levels an average of 77%, with 20% of patients having a full remission after 12 months. Patients with pituitary adenomas that abut the optic chiasm can be treated with cyberknife radiosurgery, controlling tumor growth and preserving vision in most patients. Heavy particle pituitary radiation produces a remission in about 70% of patients by 2 years and 80% of patients by 5 years. Radiation therapy eventually produces some degree of hypopituitarism in most patients. Conventional radiation therapy may cause some degree of organic brain syndrome and predisposes to small strokes. Patients must receive lifelong follow-up, with regular monitoring of serum GH and IGF-I levels. Serum GH levels over 5 ng/mL and rising IGF-I levels usually indicate a recurrent tumor.

Hypopituitarism may occur, due to the tumor itself, pituitary surgery, or radiation therapy. Hypopituitarism may develop years following radiation therapy, so patients must have regular clinical monitoring of their pituitary function.
clinically significant enlargement of a macroprolactinoma (diameter ≥ 1 cm) occurs in about 30%.

Pituitary prolactinomas may cosecrete GH and cause acromegaly (see above). Large tumors may cause headaches, visual symptoms, and pituitary insufficiency.

Aside from pituitary tumors, some women secrete an abnormal form of prolactin that appears to cause peripartum cardiomyopathy (see Chapter 10). Suppression of prolactin secretion with dopamine agonists can reverse the cardiomyopathy.

### B. Laboratory Findings

Evaluate for conditions known to cause hyperprolactinemia, particularly pregnancy (serum hCG), hypothyroidism (serum FT₄ and TSH), kidney disease (BUN and serum creatinine), cirrhosis (liver function tests) and hyperparathyroidism (serum calcium). Men are evaluated for hypogonadism with determinations of serum total and free testosterone, LH, and FSH. Women who have amenorrhea are assessed for hypogonadism with determinations of serum estradiol, LH, and FSH. Patients with pituitary macroadenomas (> 3 cm in diameter) should have PRL measured on serial dilutions of serum, since IRMA assays may otherwise report falsely low titers, the “high-dose hook effect.” Patients with macroprolactinomas or manifestations of possible hypopituitarism should be evaluated for hypopituitarism as described above. An assay for macroprolactinemia should be considered for patients with hyperprolactinemia who are relatively asymptomatic and have no apparent cause for hyperprolactinemia.

### C. Imaging

Patients with hyperprolactinemia not induced by drugs, hypothyroidism, or pregnancy should be examined by pituitary MRI. Small prolactinomas may thus be demonstrated, but clear differentiation from normal variants is not always possible. In the event that a woman with a macroprolactinoma becomes pregnant and elects not to take dopamine agonists during her pregnancy, MRI is usually not performed since the normal pituitary grows during pregnancy. However, if visual-field defects or other neurologic symptoms develop in a pregnant woman, a limited MRI study should be done, focusing on the pituitary without gadolinium contrast.

### Differential Diagnosis

The causes of hyperprolactinemia are shown in Table 26–2. Chronic nipple stimulation, nipple piercing, augmentation or reduction mammoplasty, and mastectomy may stimulate PRL secretion. The pituitary tumor of acromegaly can cosecrete GH and PRL. Hyperprolactinemia may also be idiopathic. Increased pituitary size is a normal variant in young women. About 10% of hyperprolactinemic patients are found to be secreting macroprolactin, a relatively inactive “big prolactin”; pituitary MRI is normal in 78% of cases.

The differential diagnosis for galactorrhea includes the small amount of breast milk that can be expressed from the nipple in many parous women that is not cause for concern. Nipple stimulation from nipple rings, chest surgery, or acupuncture can cause galactorrhea; serum PRL levels may be normal or minimally elevated. Some women can have galactorrhea with normal serum PRL levels and no discernible cause (idiopathic). Normal breast milk may be various colors besides white. Bloody galactorrhea requires an evaluation for breast malignancy.

### Treatment

Medications known to increase PRL should be stopped if possible. Hyperprolactinemia due to hypothyroidism is corrected by thyroxine.

Women with microprolactinomas who have amenorrhea or are desirous of contraception may safely take oral contraceptives or estrogen replacement—there is minimal risk of stimulating enlargement of the microadenoma. Patients with infertility and hyperprolactinemia may be treated with a dopamine agonist in an effort to improve fertility. Women with amenorrhea who elect to receive no treatment have an increased risk of developing osteoporosis; such women require periodic bone densitometry.

Pituitary macroadenomas (> 10 mm in diameter) have a higher risk of progressive growth, particularly during treatment with estrogen or testosterone replacement therapy or during pregnancy. Therefore, patients with macroadenomas should not be treated with sex HRT unless they are in remission with dopamine agonist medication or surgery. Pregnant women with macroadenomas

The differential diagnosis for galactorrhea includes the small amount of breast milk that can be expressed from the nipple in many parous women that is not cause for concern. Nipple stimulation from nipple rings, chest surgery, or acupuncture can cause galactorrhea; serum PRL levels may be normal or minimally elevated. Some women can have galactorrhea with normal serum PRL levels and no discernible cause (idiopathic). Normal breast milk may be various colors besides white. Bloody galactorrhea requires an evaluation for breast malignancy.
should continue to receive treatment with dopamine agonists throughout the pregnancy to prevent tumor growth. If dopamine agonists are not used during pregnancy in a woman with a macroprolactinoma, visual-field testing is required each trimester. During pregnancy, measurement of prolactin is not useful surveillance for tumor growth due to the fact that prolactin increases greatly during normal pregnancy.

A. Dopamine Agonists

Dopamine agonists are the initial treatment of choice for patients with giant prolactinomas and those with hyperprolactinemia desiring restoration of normal sexual function and fertility. Cabergoline is usually the best tolerated ergot-derived dopamine agonist. The beginning dosage is 0.25 mg orally once weekly for 1 week, then 0.25 mg twice weekly for the next week, then 0.5 mg twice weekly. Further dosage increases may be required monthly, based on serum PRL levels, up to a maximum of 1.5 mg twice weekly. Bromocriptine (1.25–20 mg/d orally) is an alternative drug. Women who experience nausea with oral preparations may find relief with deep vaginal insertion of cabergoline or bromocriptine tablets; vaginal irritation sometimes occurs. Quinagolide (Norprolac; not available in the United States) is a non-ergot-derived dopamine agonist for patients intolerant or resistant to ergot-derived medications; the starting dosage is 0.075 mg/d orally, increasing as needed and tolerated to a maximum of 0.6 mg/d. Patients whose tumor is resistant to one dopamine agonist may be switched to another in an effort to induce a tolerable remission.

Dopamine agonists are given at bedtime to minimize side effects of fatigue, nausea, dizziness, and orthostatic hypotension. These symptoms usually improve with dosage reduction and continued use. Erythromelalgia is rare. Dopamine agonists can cause a variety of psychiatric side effects that are not dose related and may take weeks to resolve once the dopamine agonist is discontinued. Therefore, dopamine agonists should be used judiciously in psychiatric patients whose antipsychotic medications have caused hyperprolactinemia. Long-term therapy with dopamine agonists (cabergoline, bromocriptine, or pergolide) for pituitary tumors has not caused the cardiac valve problems that can occur when much higher doses are used for Parkinson disease.

With dopamine agonist treatment, 90% of patients with prolactinomas experience a fall in serum PRL to 10% or less of pretreatment levels; about 80% of treated patients achieve a normal serum PRL level. Shrinkage of a pituitary adenoma occurs early, but the maximum effect may take up to 1 year. Nearly half of prolactinomas—even massive tumors—shrink more than 50%. Such shrinkage of giant prolactinomas can result in spinal fluid rhinorrhea. Discontinuing therapy after months or years usually results in the reappearance of hyperprolactinemia and galactorrhea-amennorhea. After 2 years of cabergoline therapy, the percentage of patients who maintain a normal serum prolactin after withdrawal of the drug are as follows: 32% with idiopathic hyperprolactinemia, 21% with microprolactinomas, and 16% with macroprolactinomas.

Because dopamine agonists usually restore fertility promptly, many pregnancies have resulted; no teratogenicity has been noted with any of the dopamine agonists. However, women with microadenomas may have treatment withdrawn during pregnancy. Macroadenomas may enlarge significantly during pregnancy; if therapy is withdrawn, such patients must be monitored clinically with serum PRL determinations and with computer-assisted visual fields. Women with macroprolactinomas who have responded to dopamine agonists may safely receive oral contraceptive agents as long as they continue receiving therapy.

B. Surgical Treatment

Transphenoidal pituitary surgery may be urgently required for large tumors undergoing apoplexy or those severely compromising visual fields. It is also used electively for patients who do not tolerate or respond to dopamine agonists. Pituitary transphenoidal surgery is generally well-tolerated, with a surgical mortality rate of < 0.5%. Complications, such as cerebrospinal fluid leakage, meningitis, stroke, or visual loss, occur in about 3% of cases; sinusitis, nasal septal perforation, or infection complicates about 6.5% of surgeries. Postoperative hyponatremia occurs quite commonly, and it is advisable to monitor serum sodium levels for the first 2 weeks postoperatively. For pituitary microprolactinomas, skilled neurosurgeons are successful in normalizing prolactin in 87% of patients; the 10-year recurrence rate is 13%. Pituitary function can be preserved in over 95% of cases. However, the surgical success rate for macroprolactinomas is much lower, and the complication rates are higher. Cranietomy is rarely indicated, since even large tumors can usually be decompressed via the transsphenoidal approach.

Fluid and electrolyte disturbances occur in most patients postoperatively. Diabetes insipidus can occur within 2 days postoperatively but is usually mild and self-correcting. Hyponatremia can occur abruptly 4–13 days postoperatively in 21% of patients; symptoms may include nausea, vomiting, headache, malaise, or seizure. It is treated with fluid restriction and salt supplements. It is prudent to monitor serum sodium levels postoperatively. Dietary salt supplements for 2 weeks postoperatively may help prevent this complication.

C. Radiation Therapy

Radiation therapy is reserved for patients with macroadenomas that are growing despite treatment with dopamine agonists. A single gamma knife or cyberknife treatment is preferable for certain patients whose optic chiasm is clear of tumor, since it is generally safer and more convenient than conventional radiation therapy. Conventional radiation therapy must be given over 5 weeks and carries a high risk of eventual hypopituitarism. Other possible side effects include some degree of memory impairment and an increased long-term risk of second tumors and small vessel ischemic strokes. After radiation therapy, patients are advised to take low-dose aspirin daily for life to reduce their stroke risk.

D. Chemotherapy

Some patients with aggressive pituitary macroadenomas or carcinomas are not surgical candidates and do not respond to dopamine agonists or radiation therapy. Temozolomide...
may be administered, 150–200 mg/m² orally daily for 5 days of each 28-day cycle; after three cycles, treatment efficacy is determined by prolactin measurement and MRI scanning. A minority of such patients respond to temozolamide.

### THYROID TESTING

Assays for FT₄, total triiodothyronine (T₃), and free triiodothyronine (FT₃) have largely supplanted measurements of total T₄, resin T₃ uptake (RT₃U), and free thyroxine index (FTI). It is particularly important to determine “free” serum levels (FT₄ and FT₃) in conditions associated with high circulating levels of thyroxine-binding globulin, such as during therapy with oral estrogen. Ultrasensitive assays for serum TSH have largely replaced older TSH assays. Table 26–3 shows the appropriate use of thyroid tests.

#### HYPOTHYROIDISM & MYXEDEMA

- **Essentials of Diagnosis**
  - Weakness, fatigue, cold intolerance, constipation, weight change, depression, menorrhagia, hoarseness.
  - Dry skin, bradycardia, delayed return of deep tendon reflexes.
  - Anemia, hyponatremia, hyperlipidemia.
  - FT₄ level is usually low.
  - TSH elevated in primary hypothyroidism.

#### General Considerations

Hypothyroidism is common, affecting over 1% of the general population and about 5% of individuals over age

60 years. Thyroid hormone deficiency affects almost all body functions. The degree of severity ranges from mild and unrecognized hypothyroid states to striking myxedema. The fluid retention seen in myxedema is caused by the interstitial accumulation of hydrophilic mucopolysaccharides, which leads to lymphedema. Hyponatremia is the result of impaired renal tubular sodium reabsorption due to reductions in Na+-K+-ATPase.

Hypothyroidism may be due to failure or resection of the thyroid gland itself or deficiency of pituitary TSH (see Hypopituitarism, above). The condition must be distinguished from the functional hypothyroidism that occurs in severe nonthyroidal illness, which does not require treatment with thyroxine (see Euthyroid Sick Syndrome).

Maternal hypothyroidism during pregnancy results in offspring with IQ scores that are an average 7 points lower than those of euthyroid mothers.

Goiter may be present with thyroiditis, iodide deficiency, genetic thyroid enzyme defects, drug goitrogens (lithium, iodide, propylthiouracil or methimazole, phenylbutazone, sulfonamides, amiodarone, interferon-α, interferon-β, interleukin-2), food goitrogens in iodide-deficient areas (eg, turnips, cassavas) or, rarely, peripheral resistance to thyroid hormone or infiltrating diseases (eg, cancer, sarcoidosis). A hypothyroid phase occurs in subacute (de Quervain) viral thyroiditis following initial hyperthyroidism. Hashimoto thyroiditis is the most common cause of hypothyroidism (see Thyroiditis section).

Goiter is usually absent when hypothyroidism is due to destruction of the gland by surgery, radiation therapy (to the head, neck, chest, and shoulder region), or 131I. Chemotherapy can reduce thyroid function, causing hypothyroidism. Sunitinib, a protein-tyrosine kinase inhibitor used to treat gastrointestinal stromal malignancies, causes transient primary hypothyroidism in about 50% of treated patients.

Amiodarone, because of its high iodine content, causes clinically significant hypothyroidism in about 15–20% of patients who receive it. Hypothyroidism occurs most often in patients with preexisting autoimmune thyroiditis and in patients who are not iodine-deficient. The T4 level is normal or low, and the TSH is elevated, usually over 20 ng/dL. Another 17% of patients have milder elevations of TSH and are asymptomatic. Low-dose amiodarone is less likely to cause hypothyroidism. Cardiac patients with amiodarone-induced symptomatic hypothyroidism are treated with just enough thyroxine to relieve symptoms. Hypothyroidism usually resolves over several months if amiodarone is discontinued. Hypothyroidism may also develop in patients with a high iodine intake from other sources, especially if they have underlying lymphocytic thyroiditis.

Hepatitis C is associated with an increased risk of autoimmune thyroiditis, with 21% of affected patients having antithyroid antibodies and 13% having hypothyroidism. The risk of thyroid dysfunction is even higher when patients are treated with interferon. Interferon-α and interferon-β treatment can induce thyroid dysfunction (usually hypothyroidism, sometimes hyperthyroidism) in 6% of patients. Spontaneous resolution occurs in over 50% of cases once interferon is discontinued.

Clinical Findings

A. Symptoms and Signs

1. Common manifestations—Mild hypothyroidism often escapes detection without screening (ie, serum TSH). Common symptoms of hypothyroidism include weight gain, fatigue, lethargy, depression, weakness, dyspnea on exertion, arthralgias or myalgias, muscle cramps, menorrhagia, constipation, dry skin, headache, paresthesias, carpal tunnel syndrome, cold intolerance, and Raynaud syndrome. Physical findings can include bradycardia; diastolic hypertension; thin, brittle nails; thinning of hair; peripheral edema; puffy face and eyelids; and skin pallor or yellowing (carotenemia). Delayed relaxation of deep tendon reflexes may be present. Patients often have a palpably enlarged thyroid (goiter) that arises due to elevated serum TSH levels or the underlying thyroid pathology, such as Hashimoto thyroiditis.

2. Less common manifestations—Less common symptoms of hypothyroidism include diminished appetite and weight loss, hoarseness, decreased sense of taste and smell, and diminished auditory acuity. Some patients may complain of dysphagia or neck discomfort. Although most menstruating women have menorrhagia, some women have scant menses or amenorrhea. Physical findings may include thinning of the outer halves of the eyebrows; thickening of the tongue; hard pitting edema; and effusions into the pleural and peritoneal cavities as well as into joints. Galactorrhea may also be present. Cardiac enlargement (“myxedema heart”) and pericardial effusions may occur. Psychosis (myxedema madness) can occur from severe hypothyroidism or from toxicity of other drugs whose metabolism is slowed in hypothyroidism. Hypothermia and stupor or myxedema coma, which is often associated with infection (especially pneumonia), may develop in patients with severe hypothyroidism. Pituitary enlargement due to hyperplasia of TSH-secreting cells, which is reversible following thyroid therapy, may be seen in longstanding hypothyroidism.

Some hypothyroid patients with Hashimoto thyroiditis have symptoms that are not due to hypothyroidism but rather to other autoimmune disease. Some autoimmune conditions that occur more commonly in patients with Hashimoto thyroiditis include Addison disease, hypoparathyroidism, diabetes mellitus, pernicious anemia, Sjögren syndrome, vitiligo, biliary cirrhosis, and celiac disease.

Celiac disease occurs in at least 5% of patients with hypothyroidism due to Hashimoto thyroiditis. Affected patients often have weight loss and gastrointestinal symptoms. However, many patients with celiac disease have minimal gastrointestinal symptoms but may have systemic manifestations such as fatigue, depression, osteoporosis or osteomalacia, iron deficiency anemia, short stature, delayed puberty, amenorrhea, or reduced fertility. Intestinal malabsorption may cause vitamin deficiencies with bruising due to vitamin K deficiency, hyperkeratosis due to vitamin A deficiency, bone pain due to vitamin D deficiency, or neuropathy and ataxia due to vitamin E or vitamin B12 deficiency.
B. Laboratory Findings

Hypothyroidism is a common disorder and thyroid function tests should be obtained for any patient with nonspecific symptoms or signs of hypothyroidism. The single best screening test for hypothyroidism is the serum TSH (Table 26–3). Serum TSH is increased with primary hypothyroidism but is low or normal with pituitary insufficiency. The FT₄ may be low or low-normal. Other laboratory abnormalities may often be seen: increased serum LDL cholesterol, triglycerides, lipoprotein (a), liver enzymes, and creatine kinase; increased serum PRL; and hypotension, hypoglycemia, and anemia (with normal or increased mean corpuscular volume). Serum analysis shows an increase in abnormal sperm morphology. In patients with autoimmune thyroiditis, titers of antibodies against thyroperoxidase and thyroglobulin are high; serum antinuclear antibodies (ANA) may be present and are not usually indicative of lupus.

The normal range for ultrasensitive TSH levels is generally stated to be 0.4–4.0 mU/L. However, the normal range of TSH varies with age such that newborns have a much higher normal range; children and elderly patients have a mildly higher normal range. Over 95% of normal adults have serum TSH concentrations under 3.0 mU/L. There is a high risk of finding antithyroid antibodies in patients with serum TSH in the upper range of normal, but most such patients are asymptomatic. TSH may be mildly elevated in some euthyroid individuals, especially elderly women (10% incidence). Such patients with normal FT₄ levels are considered to have “subclinical hypothyroidism,” but can have subtle manifestations of hypothyroidism (eg, fatigue, depression, hyperlipidemia) that may improve with thyroid hormone replacement. Patients who are completely asymptomatic with a mildly elevated serum TSH and normal serum FT₄ do not require levothyroxine replacement; in fact, mildly decreased thyroid function was associated with familial longevity in the Leiden Longevity Study. About 18% of patients with subclinical hypothyroidism later become definitely hypothyroid; many such patients have Hashimoto thyroiditis.

C. Imaging

Radiologic imaging is usually not necessary for patients with hypothyroidism. However, on CT or MRI, a goiter may be noted in the neck or in the mediastinum (retrosternal goiter). An enlarged thymus is frequently seen in the mediastinum in cases of autoimmune thyroiditis. In primary hypothyroidism with elevated serum TSH levels, MRI of the head will frequently show an enlargement of the pituitary gland from thyrotrophe hyperplasia; such enlargement can be mistaken for a pituitary tumor.

Differential Diagnosis

Many clinical manifestations of hypothyroidism (see above) are common in the general population without thyroid illness. The differential diagnoses are the conditions and drugs that can cause aberrations in laboratory tests, resulting in a low serum T₄ or T₃ or high serum TSH in the absence of hypothyroidism (Table 26–4). The pituitary is often quite enlarged in primary hypothyroidism, due to reversible hyperplasia of TSH-secreting cells; the concomitant hyperprolactinemia seen in hypothyroidism can lead to the mistaken diagnosis of a TSH-secreting or PRL-secreting pituitary adenoma.

Euthyroid sick syndrome should be considered in patients with abnormal thyroid function tests (eg, low serum T₄ and low levels of FT₄) without thyroid disease; conditions that can result in this syndrome include severe illness, caloric deprivation, or major surgery. Patients who have undergone major surgery may have accelerated peripheral metabolism of serum T₄ to reverse T₃ (rT₃). Furthermore, in most patients who are critically ill, there is a circulating inhibitor of thyroid hormone binding to serum thyroxine-binding proteins (TBPs). This causes the RT₃U to be misleadingly low, causing the computed FT₁ to be very low. The presence of a very low serum T₄ in severe nonthyroidal illness indicates a poor prognosis. Serum TSH tends to be suppressed in severe nonthyroidal illness, making the diagnosis of concurrent primary hypothyroidism quite difficult, although the presence of a goiter suggests the diagnosis.

Table 26–4. Factors that may cause aberrations in laboratory tests that may be mistaken for primary hypothyroidism.¹

¹True primary hypothyroidism may coexist.

1T₄, levothyroxine; T₃, triiodothyronine; TSH, thyroid-stimulating hormone.
The clinician must decide whether such severely ill patients (with a low serum T₄ but no elevated TSH) might have hypothyroidism due to pituitary insufficiency. Patients without symptoms of prior brain lesion or hypopituitarism are very unlikely to suddenly develop hypopituitarism during an unrelated illness. Patients with diabetes insipidus, hypopituitarism, or other signs of a central nervous system lesion may be given T₄ empirically.

True secondary hypothyroidism due to direct dopaminergic suppression of TSH-secreting cells may develop in patients receiving prolonged dopamine infusions.

Certain antiseizure medications cause low serum FT₄ levels by accelerating hepatic conversion of T₄ to T₃; serum TSH levels are normal.

### Complications

Cardiac complications may occur as a result of preexistent coronary artery disease and congestive heart failure, which may be exacerbated by levothyroxine therapy. Patients with severe hypothyroidism have an increased susceptibility to bacterial pneumonia. Megacolon has been described in long-standing hypothyroidism. Organic psychoses with paranoid delusions may occur (“myxedema madness”). Rarely, adrenal crisis may be precipitated by thyroid therapy. Hypothyroidism is a rare cause of infertility, which may respond to thyroid medication. Pregnancy in a woman with untreated hypothyroidism often results in miscarriage. Sellar enlargement and even well-defined TSH-secreting tumors may develop in untreated cases. These tumors decrease in size after replacement therapy is instituted.

**Myxedema crisis** refers to severe, life-threatening hypothyroidism. The manifestations of hypothyroidism are present and more severe. Affected patients have impaired cognition, ranging from confusion to somnolence to coma (myxedema coma). Convulsions and abnormal central nervous system signs may occur. Patients have severe hypothermia, hypoventilation, hyponatremia, hypoglycemia, and hypotension. Rhabdomyolysis and acute kidney injury may occur. Myxedema coma is most often seen in elderly women who have had a stroke or who have stopped taking their levothyroxine medication. It is often induced by an underlying infection; cardiac, respiratory, or central nervous system illness; cold exposure; or drug use. The mortality rate from myxedema coma is high. Myxedematous patients are unusually sensitive to opioids and average doses may result in death. Patients with severe myxedema may have hypotension that is severe and refractory to treatment.

### Treatment

Before therapy with thyroid hormone is commenced, the hypothyroid patient requires at least a clinical assessment for adrenal insufficiency and angina, for which the patient would require evaluation and treatment.

#### A. Beginning Treatment for Hypothyroidism

Levothyroxine is the preferred preparation for treating hypothyroid patients. However, patients (as a group) receiving levothyroxine replacement do not have the same sense of well-being as their peers. In response, some clinicians prescribe mixed T₄/T₃ preparations such as Armour thyroid, but levothyroxine alone renders patients clinically euthyroid as long as it is given in sufficient doses (see below).

Otherwise healthy young and middle-age adults with hypothyroidism may be treated initially with levothyroxine in doses of 25–75 mcg orally daily. The lower doses are used for very mild hypothyroidism, while higher doses are given for more symptomatic hypothyroidism. Women who are pregnant with significant hypothyroidism may begin therapy with levothyroxine at higher doses of 100–150 mcg orally daily. The levothyroxine dosage may be increased according to clinical response and serum TSH, initially trying to keep the serum TSH level between 0.4 mU/L and 2.0 mU/L. The levothyroxine dose required to render patients clinically euthyroid varies considerably, with higher doses required during pregnancy and with certain medications (see below). Since food interferes slightly with the absorption of levothyroxine, it is advisable to take levothyroxine with water in the morning after an overnight fast. The selected time should become a regular daily habit for the patient. After beginning daily administration, significant increases in serum T₄ levels are seen within 1–2 weeks, and near-peak levels are seen within 3–4 weeks.

Patients with coronary disease or those who are over age 60 years are treated with smaller initial doses of levothyroxine, 25–50 mcg orally daily; higher initial doses may be used if such patients are severely hypothyroid. The dose can be increased by 25 mcg every 1–3 weeks until the patient is euthyroid. Patients with hypothyroidism and known ischemic heart disease may begin thyroxine therapy following restoration of coronary perfusion by coronary artery angioplasty or bypass.

**Myxedema crisis** requires larger initial doses of levothyroxine intravenously, since myxedema itself can interfere with levothyroxine intestinal absorption. Levothyroxine sodium 400 mcg is given intravenously as a loading dose, followed by 50–100 mcg intravenously daily; the lower dose is given to patients with suspected coronary insufficiency. In patients with myxedema coma, liothyronine (T₃, Triostat) can be given intravenously in doses of 5–10 mcg every 8 hours for the first 48 hours. The hypothermic patient is warmed only with blankets, since faster warming can precipitate cardiovascular collapse. Patients with hypercapnia require intubation and assisted mechanical ventilation. Infections must be detected and treated aggressively. Patients in whom concomitant adrenal insufficiency is suspected are treated with hydrocortisone, 100 mg intravenously, followed by 25–50 mg every 8 hours.

#### B. Monitoring & Optimizing Treatment of Hypothyroidism

Every hypothyroid patient requires regular clinical assessments that must include interim histories and physical examinations. Clinical judgment is critical to determine the optimal levothyroxine dose for each patient. Laboratory assays supplement clinical judgment. An elevated serum TSH usually indicates the need for a higher dose of levothyroxine (see below). Unfortunately, normal serum TSH and FT₄ levels do not accurately determine that the patient is euthyroid (see below). The patient should be prescribed sufficient levothyroxine to restore a clinically euthyroid state.
while maintaining the serum T₄ within the reference range. For most patients with hypothyroidism, a stable maintenance dose of levothyroxine can usually be found.

Levothyroxine doses may need to be titrated upward after patients commence taking medications that increase the hepatic metabolism of levothyroxine (eg, carbamazepine, phenobarbital, primidone, phenytoin, rifabutin, rifampin, sunitinib, and imatinib [Gleevec]). Amiodarone can cause an increase or decrease in thyroxine dose requirements, making it necessary to closely monitor serum TSH and adjust the thyroxine dosage accordingly in these patients. Malabsorption of thyroxine can be caused by coadministration of binding substances, such as iron preparations (including iron found in multivitamins), fiber, raloxifene, sucralfate, aluminum hydroxide antacids, sevelamer, orlistat, calcium and magnesium supplements, and soy milk or soy protein supplements. Bile acid-binding resins, such as cholestyramine and colesevelam, can bind T₄ and impair its absorption even when administered 5 hours before the T₄. Proton pump inhibitors reduce gastric acidity, which interferes slightly with the absorption of levothyroxine. Gastrointestinal disorders can interfere with thyroxine absorption, including celiac disease, inflammatory bowel disease, lactose intolerance, Helicobacter pylori gastritis, and atrophic gastritis.

Different thyroxine preparations vary in their bioavailability by up to 14%. Such differences in the bioavailability of different T₄ formulations may have a subtle but significant clinical impact. It is therefore recommended that patients always continue to take the same brand name of thyroxine or the same manufacturer’s generic thyroxine. There is no standardized optimal dose of levothyroxine, so each patient’s dose must be based on careful clinical assessment. Although serum TSH levels can be helpful in determining optimal dosing, it is important to consider clinical underreplacement with levothyroxine. However, before increasing the T₄ dosage, it is important to confirm that the patient is indeed taking the medication as directed and does not have angina. It is also important to consider the following: A high TSH in a patient receiving standard replacement doses of T₄ may indicate malabsorption of levothyroxine due to concurrent administration with binding substances (see above) or with food (instead of fasting). Malabsorption of T₄ can also occur in short bowel syndrome; therapy with medium chain triglyceride oil may improve absorption. Impaired absorption of T₄ can also be caused by diarrhea of any cause or malabsorption due to concurrent celiac disease (sprue), regional enteritis, liver disease, or pancreatic exocrine insufficiency. Serum TSH may be elevated transiently in acute psychiatric illness and during recovery from nonthyroidal illness. Autoimmune disease can cause false elevations of TSH by interfering with the assay. A high TSH can also be caused by thyrotropin-secreting pituitary tumors. TSH may be increased by phenothiazines and atypical antipsychotics.

1. During pregnancy—Administering adequate levothyroxine to a hypothyroid woman is critical. The fetus is at least partially dependent on maternal T₄ for central nervous system development—particularly in the second trimester. It is therefore important to carefully monitor hypothyroid women with serum TSH (FT₄I or FT₄ levels) that stimulates thyroid hormone production. Most women with a low serum TSH in the first trimester are euthyroid. Serum FT₄I is helpful in evaluating the thyroid status of pregnant women, particularly in the first trimester. Following delivery, levothyroxine dose requirements ordinarily return to prepregnancy levels.

Serum TSH levels normally drop while FT₄I rises during the first trimester of pregnancy. This probably results from high levels of hCG (with structural homology to TSH) that stimulates thyroid hormone production. Most women with a low serum TSH in the first trimester are euthyroid. Serum FT₄I is helpful in evaluating the thyroid status of pregnant women, particularly in the first trimester. Following delivery, levothyroxine dose requirements decline.

2. Elevated serum TSH levels—This usually indicates underreplacement with levothyroxine. However, before increasing the T₄ dosage, it is important to confirm that the patient is indeed taking the medication as directed and does not have angina. It is also important to consider the following: A high TSH in a patient receiving standard replacement doses of T₄ may indicate malabsorption of levothyroxine due to concurrent administration with binding substances (see above) or with food (instead of fasting). Malabsorption of T₄ can also occur in short bowel syndrome; therapy with medium chain triglyceride oil may improve absorption. Impaired absorption of T₄ can also be caused by diarrhea of any cause or malabsorption due to concurrent celiac disease (sprue), regional enteritis, liver disease, or pancreatic exocrine insufficiency. Serum TSH may be elevated transiently in acute psychiatric illness and during recovery from nonthyroidal illness. Autoimmune disease can cause false elevations of TSH by interfering with the assay. A high TSH can also be caused by thyrotropin-secreting pituitary tumors. TSH may be increased by phenothiazines and atypical antipsychotics.

3. Normal serum TSH levels—Patients are treated with sufficient levothyroxine to achieve normal serum TSH levels of 0.4–2.0 mU/L. Patients who continue to feel hypothyroid despite a normal serum TSH may have a suboptimal serum T₄; they may respond well to higher replacement doses of levothyroxine.

4. Low or suppressed serum TSH levels—Serum TSH levels (using a sensitive assay) that are below the reference range (0.4–4.0 mU/L) are considered “low” (0.04–0.4 mU/L) or “suppressed” (≤ 0.03 mU/L). It has generally been assumed that since TSH is a sensitive test for hyperthyroidism in Graves disease, a low serum TSH in patients taking levothyroxine reliably indicates overreplacement; that assumption is proving incorrect. Certainly, if a patient taking levothyroxine has a suppressed serum TSH and manifestations of hyperthyroidism, the dosage of levothyroxine must be reduced. However, many patients with low serum TSH levels exhibit no symptoms of hyperthyroidism. For such patients, it is important to determine whether hypopituitarism or severe nonthyroidal illness is present, which can result
in low serum TSH levels without hyperthyroidism. TSH can also be reduced by certain medications, such as nonsteroidal anti-inflammatory drugs; opioids; nifedipine; verapamil; and high-dose, short-term administration of corticosteroids. Absent such conditions, a clinically euthyroid patient with a suppressed serum TSH should be given a lower dosage of levothyroxine. Patients with hypothyroid symptoms on the reduced dosage of levothyroxine may have the higher dose resumed.

Some hypothyroid patients receiving levothyroxine have hypothyroid-type symptoms, particularly persistent fatigue or weight gain, despite having low serum TSH levels. Such patients require careful assessment for concurrent illnesses such as adrenal insufficiency, hypogonadism, anemia, celiac disease, or depression. If such conditions are not present or are treated and hypothyroid-type symptoms persist despite low-normal or low TSH levels, a serum T₃ level (FT₃ in pregnancy and women receiving oral estrogens) is often helpful. If the serum T₃ level is low or low normal, the patient may benefit from an increase in levothyroxine dosage; if a definite clinical benefit is achieved, the higher dose is continued. Patients with a low serum TSH (0.04–0.4 mU/L) on replacement levothyroxine do not have any long-term increased risk of cardiovascular disease, dysrhythmias, or fractures. However, patients with suppressed serum TSH (≤ 0.03 mU/L) do have an increased risk of such side effects and long-term monitoring for atrial arrhythmias and osteoporosis is recommended.

| Prognosis |

Hypothyroidism caused by interferon-α resolves within 17 months of stopping the drug in 50% of patients. Patients with mild hypothyroidism caused by Hashimoto thyroiditis have a remission rate of 11%. With early treatment of hypothyroidism, striking transformations take place both in appearance and mental function. Return to a normal state is usually the rule, but relapses will occur if treatment is interrupted. On the whole, response to thyroid treatment is usually the rule, but relapses will occur if treatment is interrupted. On the whole, response to thyroid treatment is usually the rule, but relapses will occur if treatment is interrupted.

### A. Graves Disease

Graves disease (known as Basedow disease in Europe) is the most common cause of thyrotoxicosis. It is an autoimmune disorder affecting the thyroid gland, characterized by an increase in synthesis and release of thyroid hormones. Graves disease is much more common in women than in men (8:1), and its onset is usually between the ages of 20 and 40 years. It may be accompanied by infiltrative ophthalmopathy (Graves ophthalmos) and, less commonly, by infiltrative dermopathy (pretibial myxedema). The thymus gland is typically enlarged and serum ANA levels are usually elevated, reflecting the underlying autoimmunity. Graves disease has a familial tendency, and many patients have a family history of Graves disease or hypothyroidism from Hashimoto thyroiditis. Histocompatibility studies have shown an association with group HLA-B8 and HLA-DR3. The pathogenesis of the hyperthyroidism of Graves disease involves the formation of autoantibodies that bind to the TSH receptor in thyroid cell membranes and stimulate the gland to hyperfunction. Such antibodies are called thyroid-stimulating immunoglobulins (TSI) or TSH receptor antibodies (TSHrAb).

Dietary iodine supplementation can trigger Graves disease. An increased incidence of Graves disease occurs in countries that have embarked on national programs to fortify commercial salt with potassium iodide; the increase in Graves disease lasts about 4 years. Similarly, patients being treated with potassium iodide or amiodarone (which contains iodine) have an increased risk of developing Graves disease.

Patients with Graves disease have an increased risk of other systemic autoimmune disorders. Affected patients are at increased risk for Sjögren syndrome, pernicious anemia,
Addison disease, alopecia areata, vitiligo, celiac disease, autoimmune diabetes mellitus type 1, hypoparathyroidism, Addison disease, alopecia areata, vitiligo, celiac disease, autoimmune diabetes mellitus type 1, hypoparathyroidism, and cardiomyopathy.

B. Toxic Multinodular Goiter and Thyroid Adenomas

Autonomous toxic adenomas of the thyroid may be single (Plummer disease) or multiple (toxic multinodular goiter). Jod-Basedow disease, or iodine-induced hyperthyroidism, may occur in patients with multinodular goiters after intake of large amounts of iodine in the diet or in the form of radiographic contrast materials or drugs, especially amiodarone. This condition is not associated with infiltrative ophthalmopathy or dermopathy.

C. Subacute (de Quervain) Thyroiditis

Subacute thyroiditis typically presents with a moderately enlarged, tender thyroid, and hyperthyroidism. It is thought to be due to a viral infection. If the gland is nontender, the disorder is called “silent thyroiditis.” Hyperthyroidism is followed by hypothyroidism. Patients taking lithium may rarely experience thyrotoxicosis due to silent thyroiditis. Symptoms mimic a manic episode such that the diagnosis is often missed.

D. Thyrotoxicosis Factitia

Thyrotoxicosis factitia is due to ingestion of excessive amounts of exogenous thyroid hormone. Isolated epidemics of thyrotoxicosis have been caused by consumption of ground beef contaminated with bovine thyroid gland.

E. Struma Ovarii

Thyroid tissue is contained in about 3% of ovarian dermoid tumors and teratomas. This thyroid tissue may autonomously secrete thyroid hormone due to a toxic nodule or in concert with the woman’s thyroid gland in Graves disease or toxic multinodular goiter.

F. Pituitary Tumor

TSH hypersecretion by the pituitary may be caused by a tumor or thyrotoxic cell hyperplasia and is a rare cause of hyperthyroidism. Serum TSH is elevated or normal in the presence of true thyrotoxicosis. Pituitary hyperplasia may be detected on MRI scan as pituitary enlargement without a discrete adenoma being visible. This condition appears to be due to a diminished feedback effect of T₄ upon the pituitary. Some cases are familial. Prolonged untreated hypothyroidism causes pituitary enlargement due to thyrotrope hyperplasia; thyrotoxic tumors are rare.

G. Thyroiditis

Hashimoto thyroiditis may cause transient hyperthyroidism during the initial destructive phase. This is also seen in some patients receiving interferon-α, interferon-β, and interleukin-2. Postpartum thyroiditis refers to Hashimoto thyroiditis that occurs in the first 6 months after delivery. It is common, occurring postpartum in 5–10% of women in the United States. Hyperthyroidism results from the release of stored thyroid hormone following damage to the thyroid. Thyroiditis and hyperthyroidism can also develop in patients receiving sunitinib chemotherapy.

H. Pregnancy and Trophoblastic Tumors

The prevalence of hyperthyroidism in pregnancy—most commonly due to Graves disease—is about 0.2%. Struma ovarii is rare. Newborns have an increased risk of intrauterine growth retardation, prematurity, and transient thyrotoxicosis from transplacental transfer of thyrotropin receptor antibody (TRAb).

Although hCG generally has a low affinity for the thyroid’s TSH receptors, very high serum levels of hCG may cause sufficient receptor activation to cause thyrotoxicosis. Mild gestational hyperthyroidism may occur during the first 4 months of pregnancy, when hCG levels are very high. Pregnant women are more likely to have thyrotoxicosis and hyperemesis gravidarum if they have high serum levels of asialo-hCG, a subfraction of hCG with greater affinity for TSH receptors.
High levels of hCG can also cause thyrotoxicosis in some cases of molar pregnancy, choriocarcinoma, and testicular malignancies.

I. Thyroid Carcinoma

Metastatic functioning thyroid carcinoma is a rare cause of thyrotoxicosis. Hyperthyroidism can be induced by recombinant human thyroid-stimulating hormone (rhTSH) that is given prior to radioiodine therapy or scanning. (See Thyroid Cancer section.)

J. Iodine-Induced Hyperthyroidism

Iodine-induced hyperthyroidism is also known as Jod-Basedow disease. The recommended iodine intake for nonpregnant adults is 150 mcg/d. Higher iodine intake can precipitate hyperthyroidism, particularly in patients with nodular goiters, autonomous thyroid nodules, or asymptomatic Graves disease. Iodine-induced hyperthyroidism also occurs in patients with no detectable underlying thyroid disorder. Common sources of excess iodine include intravenous iodinated radiocontrast dye, certain foods (eg, kelp, nori), topical iodinated antisepsics (eg, povidine iodine), and medications (eg, potassium iodide or amiodarone). Intravenous iodinated radiocontrast dye can also precipitate thyrotoxicosis by inducing a destructive subacute thyroiditis that may be painful and is similar to type 2 amiodarone-induced thyrotoxicosis.

K. Amiodarone-Induced Thyrotoxicosis

Amiodarone is a widely used antiarrhythmic drug. The half-life of amiodarone and its metabolites is about 100 days. By weight, amiodarone is 37% iodine and thyroid dysfunction develops in about 15–20% of patients taking amiodarone. In the United States, amiodarone-induced thyrotoxicosis develops in about 3% of patients taking the drug; the incidence of amiodarone-induced thyrotoxicosis is higher in Europe and in iodine-deficient geographic areas (20%). Hyperthyroidism can occur 4 months to 100 days. By weight, amiodarone is 37% iodine and thyroid dysfunction develops in about 3% of patients taking the drug; the incidence of amiodarone-induced thyrotoxicosis is higher in Europe and in iodine-deficient geographic areas (20%). Hyperthyroidism can occur 4 months to 100 days. By weight, amiodarone is 37% iodine and thyroid dysfunction develops in about 3% of patients taking the drug; the incidence of amiodarone-induced thyrotoxicosis is higher in Europe and in iodine-deficient geographic areas (20%). Hyperthyroidism can occur 4 months to 100 days. By weight, amiodarone is 37% iodine and thyroid dysfunction develops in about 3% of patients taking the drug; the incidence of amiodarone-induced thyrotoxicosis is higher in Europe and in iodine-deficient geographic areas (20%). Hyperthyroidism can occur 4 months to 100 days. By weight, amiodarone is 37% iodine and thyroid dysfunction develops in about 3% of patients taking the drug; the incidence of amiodarone-induced thyrotoxicosis is higher in Europe and in iodine-deficient geographic areas (20%). Hyperthyroidism can occur 4 months to 100 days.
Exophthalmometry should be performed on all patients with Graves disease to document their degree of exophthal- mos and detect progression of orbitopathy. The protrusion of the eye beyond the orbital rim is measured with a prism instrument (Hertel exophthalmometer). Maximum normal eye protrusion varies between kindreds and races, being about 22 mm for blacks, 20 mm for whites, and 18 mm for Asians.

The differential diagnosis for Graves orbitopathy includes diplopia caused by coexistent ocular myasthenia gravis, which is more common in Graves disease and is usually mild, often with selective eye involvement. Acetylcholinesterase receptor antibody (AChR Ab) levels are elevated in only 36% of such patients, and a thymoma is present in 9%. Orbital lymphoma can also masquerade as Graves orbitopathy.

Graves dermopathy (pretibial myxedema) occurs in about 3% of patients with Graves disease, usually in the pretibial region. It is more common in patients with high levels of serum thyroid-stimulating immunoglobulin and in those with severe Graves ophthalmopathy. Glycosaminoglycans accumulation and lymphoid infiltration occur in affected skin, which becomes erythematous with a thickened, rough texture. Elephantiasis of the legs is a rare complication.

Thyroid acropathy is an extreme and unusual manifestation of Graves disease. It presents with digital clubbing, swelling of fingers and toes, and a periosteal reaction of extremity bones. It is ordinarily associated with orbitopathy and thyroid dermopathy. Most patients are smokers. The presence of thyroid acropathy is an indication of the severity of the autoimmunity; most patients have high serum titers of thyroid-stimulating immunoglobulin. Patients with thyroid acropathy are at greater risk for having concurrent Graves dermopathy and severe ophthalmopathy. However, acropathy itself does not usually cause clinical complaints.

Tetany is a rare presenting feature. In hyperthyroidism, the renal excretion of magnesium is increased and hypomagnesemia is common. Severe magnesium depletion causes hypoparathyroidism that can result in hypocalcemia.

Hyperthyroidism during pregnancy shares many of the features of normal pregnancy: tachycardia, warm skin, heat intolerance, increased sweating, and a palpable thyroid. Pregnancy can have a beneficial effect on the thyrotoxicosis of Graves disease. However, there is an increased risk of thyroid storm, preeclampsia–eclampsia, congestive heart failure, premature delivery, and abruptio placenta. TSI (or TSHrAb) crosses the placenta; if maternal serum TSI (or TSHrAb) levels reach > 500% in the third trimester, the risk of transient neonatal Graves disease in the newborn is increased.

Hypokalemic periodic paralysis occurs in about 15% of Asian or Native American men with thyrotoxicosis. It usually presents abruptly with symmetric flaccid paralysis (and few thyrotoxic symptoms), often after intravenous dextrose, oral carbohydrate, or vigorous exercise. Attacks last 7–72 hours.

B. Laboratory Findings

Serum FT₄, T₃, FT₃, T₄, thyroid resin uptake, and FT₄ index are all usually increased. Sometimes the FT₃ level may be normal but with an elevated serum T₄ (T₄ toxicosis). Serum T₃ can be misleadingly elevated when blood is collected in tubes using a gel barrier, which causes certain immunoas-
says (eg, Immulite but not Axsym analyzers) to report serum total T₄ levels that are falsely elevated in 24% of normal patients. Serum T₃ or T₄ can be elevated in other nonthyroidal conditions (Table 26–5).

Serum TSH is suppressed in hyperthyroidism, except in the very rare cases of pituitary inappropriate secretion of thyrotopin. Serum TSH may be misleadingly low in other nonthyroidal conditions (Table 26–5). The term “subclinical hyperthyroidism” is used to describe asymptomatic individuals with a low serum TSH but normal serum levels of FT₃ and T₄; progression to symptomatic thyrotoxicosis occurs at a rate of 1–2% per year in patients without a goiter and at a rate of 5% per year in patients with a multinodular goiter.

Hyperthyroidism can cause other laboratory abnormalities, including hypercalcemia, increased alkaline phosphatase, anemia, and decreased granulocytes. Hypokalemia and hypophosphatemia occur in thyrotoxic periodic paralysis.

Problems of diagnosis occur in patients with acute psychiatric disorders; about 30% of these patients have elevated serum T₄ levels without clinical thyrotoxicosis. The TSH is not usually suppressed, distinguishing psychiatric disorder from true hyperthyroidism. T₄ levels return to normal gradually.

In Graves disease, serum TSI (or TSHrAb) is usually detectable (65%). Antithyroglobulin or antithyroperoxidase antibodies are usually elevated but are nonspecific. Serum ANA and anti-double-stranded DNA antibodies are also usually elevated without any evidence of lupus erythematosus or other collagen-vascular disease.

With subacute thyroiditis, patients often have an increased erythrocyte sedimentation rate (ESR) but antithyroid antibodies are usually not present in the plasma, and tests for TSI (or TSHrAb) are negative. Patients with iodine-induced hyperthyroidism also have undetectable serum TSI (or TSHrAb), an absence of serum anti-thyroperoxidase antibodies, and an elevated urinary iodine concentration. In thyrotoxicosis facticia, serum thyro- globulin levels are low, distinguishing it from other causes of hyperthyroidism.

With hyperthyroidism during pregnancy, women have an elevated FT₄ while the TSH is suppressed. However, apparent lack of full TSH suppression can be seen due to misidentification of hCG as TSH in certain assays. Although the total T₄ is elevated in most pregnant women, values over 20 mcg/dL are encountered only in hyperthyroidism. The T₃ resin uptake, which is low in normal pregnancy because of high TBG concentration, is normal or high in thyrotoxic persons. Pregnancy can have a beneficial effect on the thyrotoxicosis of Graves disease, with decreasing antibody titers and decreasing FT₄ levels as the pregnancy advances.

Hypokalemic periodic paralysis occurs in about 15% of Asian or Native American men with thyrotoxicosis. It usually presents abruptly with symmetric flaccid paralysis (and few thyrotoxic symptoms), often after intravenous dextrose, oral carbohydrate, or vigorous exercise. Attacks last 7–72 hours.

B. Laboratory Findings

Serum FT₄, T₃, FT₃, T₄, thyroid resin uptake, and FT₄ index are all usually increased. Sometimes the FT₃ level may be normal but with an elevated serum T₄ (T₄ toxicosis). Serum T₃ can be misleadingly elevated when blood is collected in tubes using a gel barrier, which causes certain immunoas-
says (eg, Immulite but not Axsym analyzers) to report serum total T₄ levels that are falsely elevated in 24% of normal patients. Serum T₃ or T₄ can be elevated in other nonthyroidal conditions (Table 26–5).

Serum TSH is suppressed in hyperthyroidism, except in the very rare cases of pituitary inappropriate secretion of thyrotopin. Serum TSH may be misleadingly low in other nonthyroidal conditions (Table 26–5). The term “subclinical hyperthyroidism” is used to describe asymptomatic individuals with a low serum TSH but normal serum levels of FT₃ and T₄; progression to symptomatic thyrotoxicosis occurs at a rate of 1–2% per year in patients without a goiter and at a rate of 5% per year in patients with a multinodular goiter.

Hyperthyroidism can cause other laboratory abnormalities, including hypercalcemia, increased alkaline phosphatase, anemia, and decreased granulocytes. Hypokalemia and hypophosphatemia occur in thyrotoxic periodic paralysis.

Problems of diagnosis occur in patients with acute psychiatric disorders; about 30% of these patients have elevated serum T₄ levels without clinical thyrotoxicosis. The TSH is not usually suppressed, distinguishing psychiatric disorder from true hyperthyroidism. T₄ levels return to normal gradually.

In Graves disease, serum TSI (or TSHrAb) is usually detectable (65%). Antithyroglobulin or antithyroperoxidase antibodies are usually elevated but are nonspecific. Serum ANA and anti-double-stranded DNA antibodies are also usually elevated without any evidence of lupus erythematosus or other collagen-vascular disease.

With subacute thyroiditis, patients often have an increased erythrocyte sedimentation rate (ESR) but antithyroid antibodies are usually not present in the plasma, and tests for TSI (or TSHrAb) are negative. Patients with iodine-induced hyperthyroidism also have undetectable serum TSI (or TSHrAb), an absence of serum anti-thyroperoxidase antibodies, and an elevated urinary iodine concentration. In thyrotoxicosis facticia, serum thyroglobulin levels are low, distinguishing it from other causes of hyperthyroidism.

With hyperthyroidism during pregnancy, women have an elevated FT₄ while the TSH is suppressed. However, apparent lack of full TSH suppression can be seen due to misidentification of hCG as TSH in certain assays. Although the total T₄ is elevated in most pregnant women, values over 20 mcg/dL are encountered only in hyperthyroidism. The T₃ resin uptake, which is low in normal pregnancy because of high TBG concentration, is normal or high in thyrotoxic persons. Pregnancy can have a beneficial effect on the thyrotoxicosis of Graves disease, with decreasing antibody titers and decreasing FT₄ levels as the pregnancy advances.

Since high levels of T₄ and FT₄ are normally seen in patients taking amiodarone, suppressed TSH (sensitive assay) must be present along with a greatly elevated T₄ (> 20 mcg/dL) or T₃ (> 200 ng/dL) in order to diagnose hyperthyroidism. (Note: Hypothyroidism occurs in an additional 6% of patients receiving amiodarone after
 interleukin-6 (IL-6) are usually quite elevated.

In type 1 amiodarone-induced thyrotoxicosis, the presence of proptosis, thyroid-stimulating immunoglobulin is diagnostic. In type 2 amiodarone-induced thyrotoxicosis, serum levels of interleukin-6 (IL-6) are usually quite elevated.

C. Imaging

RAI should never be administered to pregnant women. In others, RAI scanning and uptake may be helpful to determine the cause for hyperthyroidism. RAI uptake and scanning is not necessary for patients with obvious Graves disease who have elevated serum thyroid-stimulating immunoglobulin or associated Graves ophthalmopathy. Women with hyperthyroidism due to Graves disease should ideally have the RAI scan extended to include the pelvis in order to screen for concomitant struma ovarii (rare). A high RAI uptake is seen in Graves disease and toxic nodular goiter. Patients with type 1 amiodarone-induced thyrotoxicosis have RAI uptake that is usually detectable but typically below the normal range, although some patients may have elevated RAI uptake. A low RAI uptake is characteristic of subacute thyroiditis and iodine-induced hyperthyroidism. Low RAI uptake is also seen with interleukin-2 therapy and after neck surgery for hyperparathyroidism. In type 2 amiodarone-induced thyrotoxicosis, thyroid RAI uptake is usually below 3%.

Thyroid ultrasound can be helpful in patients with hyperthyroidism, particularly in patients with palpable thyroid nodules. Color flow Doppler sonography is helpful to distinguish type 1 amiodarone-induced thyrotoxicosis, with its increased blood flow velocity and vascularity, from type 2 amiodarone-induced thyrotoxicosis (reduced vascularity).

MRI and CT scanning of the orbits are the imaging methods of choice to visualize Graves ophthalmopathy affecting the extraocular muscles. Imaging is required only in severe or unilateral cases or in euthyroid exophthalmos affecting the extraocular muscles. Imaging is required only in severe or unilateral cases or in euthyroid exophthalmos that must be distinguished from orbital pseudotumor, tumors, and other lesions.

Differential Diagnosis

True thyrotoxicosis must be distinguished from those conditions that elevate serum T₄ and T₃ or suppress serum TSH without affecting clinical status (see Table 26–5).

Some states of hypermetabolism without thyrotoxicosis—notably severe anemia, leukemia, polycthemia, and cancer—rarely cause confusion. Pheochromocytoma is often associated with hypermetabolism, tachycardia, weight loss, and profuse sweating. Acromegaly may also produce tachycardia, sweating, and thyroid enlargement. Appropriate laboratory tests will easily distinguish these entities.

Cardiac disease (eg, atrial fibrillation, angina) refractory to treatment suggests the possibility of underlying (“apathetic”) hyperthyroidism. Other causes of ophthalmoplegia (eg, myasthenia gravis) and exophthalmos (eg, orbital tumor, pseudotumor) must be considered. Thyrotoxicosis must also be considered in the differential diagnosis of muscle weakness and osteoporosis. Diabetes mellitus and Addison disease may coexist with thyrotoxicosis.

Complications

Hypercalcemia, osteoporosis, and nephrocalcinosis may occur. Decreased libido, erectile dysfunction, diminished sperm motility, and gynecomastia may be noted in men with hyperthyroidism. Other complications include cardiac arrhythmias and heart failure, thyroid crisis, ophthalmopathy, dermopathy, and thyrotropic hypokalemic periodic paralysis (see below.)

Treatment

A. Graves Disease

1. Propranolol—Propranolol is generally used for symptomatic relief until the hyperthyroidism is resolved. It effectively relieves the tachycardia, tremor, diaphoresis, and anxiety that occur with hyperthyroidism due to any cause. It is the initial treatment of choice for thyroid storm. The periodic paralysis seen in association with thyrotoxicosis is also effectively treated with β-blockade. It has no effect on thyroid hormone secretion. Treatment is usually begun with propranolol ER 60 mg orally once or twice daily, with dosage increases every 2–3 days to a maximum daily dose of 320 mg. Propranolol ER is initially given every 12 hours for patients with severe hyperthyroidism, due to accelerated metabolism of the propranolol; it may be given once daily as hyperthyroidism improves.

2. Thiourea drugs—Methimazole or propylthiouracil is generally used for young adults or patients with mild thyrotoxicosis, small goiters, or fear of isotopes. Carbimazole is another thiourea that is converted to methimazole in vivo and is available outside the United States. Elderly patients usually respond particularly well. These drugs are also useful for preparing hyperthyroid patients for surgery and elderly patients for RAI treatment. The drugs do not permanently damage the thyroid and are associated with a lower chance of posttreatment hypothyroidism (compared with RAI or surgery). When thiourea therapy is discontinued, there is a high recurrence rate for hyperthyroidism (about 50%). A better likelihood of long-term remission is seen in patients with small goiters or mild hyperthyroidism and those requiring small doses of thiourea. Patients whose thyroperoxidase and thyroglobulin antibodies remain high after 2 years of therapy have been reported to have only a 10% rate of relapse. Thiourea therapy may be continued long-term for patients who are tolerating it well.

Agranulocytosis occurs in about 0.3% of patients taking methimazole and about 0.4% of patients taking propylthiouracil. Agranulocytosis usually occurs in the first 60 days of therapy, and it develops in a few patients after 5 months of therapy. There is a genetic tendency to develop agranulocytosis with thiourea therapy; if a close relative has had this adverse reaction, other therapies should be considered for the patient. Patients are warned that if a sore throat or febrile illness develops, they should seek medical attention and have a WBC determined immediately. The agranulocytosis is generally reversible; recovery is not

2–39 weeks of therapy.) In type 1 amiodarone-induced thyrotoxicosis, the presence of proptosis, thyroid-stimulating immunoglobulin is diagnostic. In type 2 amiodarone-induced thyrotoxicosis, serum levels of interleukin-6 (IL-6) are usually quite elevated.

C. Imaging

RAI should never be administered to pregnant women. In others, RAI scanning and uptake may be helpful to determine the cause for hyperthyroidism. RAI uptake and scanning is not necessary for patients with obvious Graves disease who have elevated serum thyroid-stimulating immunoglobulin or associated Graves ophthalmopathy. Women with hyperthyroidism due to Graves disease should ideally have the RAI scan extended to include the pelvis in order to screen for concomitant struma ovarii (rare). A high RAI uptake is seen in Graves disease and toxic nodular goiter. Patients with type 1 amiodarone-induced thyrotoxicosis have RAI uptake that is usually detectable but typically below the normal range, although some patients may have elevated RAI uptake. A low RAI uptake is characteristic of subacute thyroiditis and iodine-induced hyperthyroidism. Low RAI uptake is also seen with interleukin-2 therapy and after neck surgery for hyperparathyroidism. In type 2 amiodarone-induced thyrotoxicosis, thyroid RAI uptake is usually below 3%.

Thyroid ultrasound can be helpful in patients with hyperthyroidism, particularly in patients with palpable thyroid nodules. Color flow Doppler sonography is helpful to distinguish type 1 amiodarone-induced thyrotoxicosis, with its increased blood flow velocity and vascularity, from type 2 amiodarone-induced thyrotoxicosis (reduced vascularity).

MRI and CT scanning of the orbits are the imaging methods of choice to visualize Graves ophthalmopathy affecting the extraocular muscles. Imaging is required only in severe or unilateral cases or in euthyroid exophthalmos that must be distinguished from orbital pseudotumor, tumors, and other lesions.

Differential Diagnosis

True thyrotoxicosis must be distinguished from those conditions that elevate serum T₄ and T₃ or suppress serum TSH without affecting clinical status (see Table 26–5).

Some states of hypermetabolism without thyrotoxicosis—notably severe anemia, leukemia, polycythemia, and cancer—rarely cause confusion. Pheochromocytoma is often associated with hypermetabolism, tachycardia, weight loss, and profuse sweating. Acromegaly may also produce tachycardia, sweating, and thyroid enlargement. Appropriate laboratory tests will easily distinguish these entities.

Cardiac disease (eg, atrial fibrillation, angina) refractory to treatment suggests the possibility of underlying (“apathetic”) hyperthyroidism. Other causes of ophthalmoplegia (eg, myasthenia gravis) and exophthalmos (eg, orbital tumor, pseudotumor) must be considered. Thyrotoxicosis must also be considered in the differential diagnosis of muscle weakness and osteoporosis. Diabetes mellitus and Addison disease may coexist with thyrotoxicosis.
improved by filgrastim (granulocyte colony-stimulating factor [G-CSF]). Periodic surveillance of the WBC during treatment has been advocated, but the onset of agranulocytosis is generally abrupt.

Other side effects common to thiourea drugs include pruritus, allergic dermatitis, nausea, and dyspepsia. Anti-histamines may control mild pruritus without discontinuation of the drug. Since the two thiourea drugs are similar, patients who have had a major allergic reaction from one should not be given the other.

Primary hypothyroidism may occur. The patient may become clinically hypothyroid for 2 weeks or more before TSH levels rise, having been suppressed by the preceding hyperthyroidism. Therefore, the patient’s changing thyroid status is best monitored clinically and with serum levels of FT₄. Rapid growth of the goiter usually occurs if prolonged hypothyroidism is allowed to develop; the goiter may sometimes become massive but usually regresses rapidly with reduction or cessation of thiourea therapy or with thyroid hormone replacement.

A. Methimazole—Methimazole is generally preferred over propylthiouracil since methimazole is more convenient to use and is less likely to cause fulminant hepatic necrosis. Methimazole therapy is also less likely to cause "131I treatment failure. Rare complications peculiar to methimazole include serum sickness, cholestatic jaundice, loss of taste, alopecia, nephrotic syndrome, and hypoglycemia. Methimazole is given orally in initial doses of 30–60 mg once daily. Some patients with very mild hyperthyroidism may respond well to smaller initial doses of methimazole (10–20 mg daily). Methimazole may also be administered twice daily to reduce the likelihood of gastrointestinal upset. Methimazole use in pregnancy has been associated with a possibly increased risk of fetal anomalies such as aplasia cutis, esophageal atresia, and coanal atresia. However, methimazole may be used if the patient cannot tolerate propylthiouracil (see below). If methimazole is used during pregnancy or breastfeeding, the dose should not exceed 20 mg daily. The dosage is reduced as manifestations of hyperthyroidism resolve and as the FT₄ level falls toward normal. For patients who have elected to receive ¹³¹I therapy, methimazole is discontinued 4 days prior to receiving the ¹³¹I and is resumed at a lower dose 3 days afterwards to avoid recurrence of hyperthyroidism. About 4 weeks after ¹³¹I therapy, methimazole may be discontinued if the patient is euthyroid.

B. Propylthiouracil—Propylthiouracil has been the drug of choice during breastfeeding since it is not concentrated in the milk as much as methimazole. Propylthiouracil is also favored during pregnancy, possibly causing fewer problems in the newborn. Rare complications peculiar to propylthiouracil include arthritis, lupus, aplastic anemia, thrombocytopenia, and hypoprothrombinemia. Acute hepatitis occurs rarely and is treated with prednisone but may progress to liver failure. Propylthiouracil is given orally in initial doses of 300–600 mg daily in four divided doses. The dosage and frequency of administration are reduced as symptoms of hyperthyroidism resolve and the FT₄ level approaches normal. During pregnancy, the dose of propylthiouracil is kept below 200 mg/d to avoid goitrous hypothyroidism in the infant; the patient may be switched to methimazole in the second trimester.

3. Iodinated contrast agents—These agents provide effective temporary treatment for thyrotoxicosis of any cause. Iopanoic acid (Telepaque) or ipodate sodium (Bilivist, Oragrafin) is given orally in a dosage of 500 mg twice daily for 3 days, then 500 mg once daily. These agents inhibit peripheral 5'-monodeiodination of T₄ thereby blocking its conversion to active T₃. Within 24 hours, serum T₃ levels fall an average of 62%. For patients with Graves disease, methimazole is begun first to block iodine organification; the next day, ipodate sodium or iopanoic acid may be added. The iodinated contrast agents are particularly useful for patients who are very symptomatically thyrotoxic (see Thyroid Storm). They offer a therapeutic option for patients with T₃ overdose, subacute thyroiditis, and amiodarone-induced thyrotoxicosis and for those intolerant to thioureas and for newborns with thyrotoxicosis (due to maternal Graves disease). Treatment periods of 8 months or more are possible, but efficacy tends to wane with time. In Graves disease, thyroid RAI uptake may be suppressed during treatment but typically returns to pre-treatment uptake by 7 days after discontinuation of the drug, allowing ¹³¹I treatment.

4. Radioactive iodine (¹³¹I, RAI)—The administration of ¹³¹I is an excellent method of destroying overactive thyroid tissue (either diffuse or toxic nodular goiter). There are ample data to conclude that patients who are treated with RAI in adulthood do not have an increased risk of subsequent thyroid cancer, leukemia, or other malignancies. Similarly, individuals who were treated with RAI as teenagers have not shown any increased risk of malignancy in a 36-year retrospective study. Children born to parents previously treated with ¹³¹I show normal rates of congenital abnormalities.

Because fetal radiation is harmful, RAI should not be given to pregnant women. A sensitive pregnancy test (serum β-hCG) should be obtained on all women of reproductive age prior to ¹³¹I therapy.

Most patients may receive ¹³¹I while being symptomatically treated with propranolol ER, which is then reduced in dosage as hyperthyroxinemia resolves. However, some patients (those with coronary disease, the elderly, or those with severe hyperthyroidism) are usually rendered euthyroid with a thiouracil drug (see above) while the dosage of propranolol is reduced. A higher rate of ¹³¹I treatment failure has been reported in patients with Graves disease who have been receiving methimazole or propylthiouracil. However, therapy with ¹³¹I will usually be effective if the methimazole is discontinued at least 4 days before RAI therapy and if the therapeutic dosage of ¹³¹I is adjusted (upward) according to RAI uptake on the pretherapy scan. Prior to ¹³¹I therapy, patients are instructed against receiving intravenous iodinated contrast or ingesting large quantities of dietary iodine, but severe restriction of dietary iodine is not usually necessary.

Following ¹³¹I treatment for hyperthyroidism, Graves ophthalmopathy appears or worsens in 15% of patients (23% in smokers and 6% in nonsmokers) and improves in
none, whereas during treatment with methimazole, ophthalmopathy worsens in 3% and improves in 2% of patients. Among patients receiving prednisone following 131I treatment, preexistent ophthalmopathy worsens in none and improves in 67%. Therefore, patients with Graves ophthalmopathy who are to be treated with radioiodine should be considered for prophylactic prednisone (20–40 mg/d) for 2 months following administration of 131I, particularly in patients who have severe orbital involvement.

Smoking increases the risk of having a flare in ophthalmopathy following 131I treatment and also reduces the effectiveness of prednisone treatment. Therefore, patients who smoke are strongly encouraged to quit prior to 131I treatment.

FT4 levels may sometimes drop within 2 months after 131I treatment, but then rise again to thyrotoxic levels, at which time thyroid RAI uptake is low. This phenomenon is caused by a release of stored thyroid hormone from injured thyroid cells and does not indicate a treatment failure. In fact, serum FT4 then falls abruptly to hypothyroid levels.

There is a high incidence of hypothyroidism in the months to years after 131I, even when small doses are given. Patients with Graves disease treated with 131I also have an increased lifetime risk of developing hyperparathyroidism, particularly when radioiodine therapy was administered in childhood or adolescence. Lifelong clinical follow-up is mandatory, with measurements of serum TSH, FT4, and calcium when indicated.

### 5. Thyroid surgery

Thyroidectomy may be performed for pregnant women whose thyrotoxicosis is not controlled with low doses of thioureas, and for women who desire to become pregnant in the very near future. Surgery is also an option for nodular goiters, when there is a suspicion for malignancy.

The Hartley–Dunhill operation is the procedure of choice for patients with Graves disease having surgery; this operation consists of a total resection of one lobe and a subtotal resection of the other lobe, leaving about 4 g of thyroid tissue. Subtotal thyroidectomy of both lobes is often used, but ultimately results in a 9% recurrence rate for hyperthyroidism. Total thyroidectomy of both lobes poses an increased risk of hypoparathyroidism and damage to the recurrent laryngeal nerves.

Patients are ordinarily rendered euthyroid preoperatively with a thiourea drug. Ipodate sodium or iopanoic acid (500 mg orally twice daily) may be used in addition to a thiourea to accelerate the decline in serum T4. Propranolol ER is given orally at initial doses of 60–80 mg twice daily and increased every 2–3 days until the heart rate is < 90 beats per minute. Propranolol is continued until the serum T4 (or free T4) is normal preoperatively. Thyroid vascularity is reduced by preoperative treatment with either ipodate sodium or iopanoic acid (500 mg twice orally for 3 days) or iodine (eg, Lugol solution, two or three drops orally daily for several days). If a patient undergoes surgery while thyrotoxic, larger doses of propranolol are given perioperatively to reduce the likelihood of thyroid crisis.

Morbidity includes possible damage to the recurrent laryngeal nerve, with resultant vocal cord paralysis. If both recurrent laryngeal nerves are damaged, airway obstruction may develop, and the patient may require intubation and tracheostomy. Hypoparathyroidism also occurs, which means that calcium levels must be checked postoperatively. When a competent, experienced neck surgeon performs a thyroidectomy, surgical complications are uncommon. Thyroid surgery should be performed as an inpatient, with at least an overnight observational period.

### B. Toxic Solitary Thyroid Nodules

Toxic solitary thyroid nodules are usually benign but may rarely be malignant. If a nonsurgical therapy is elected, the nodule should be evaluated with a fine-needle aspiration biopsy (FNA). Hyperthyroidism caused by a single hyperfunctioning thyroid nodule may be treated symptomatically with propranolol ER and methimazole or propylthiouracil, as in Graves disease (see above). Patients who tolerate methimazole well may elect to continue it for long-term therapy. The dose of methimazole should be adjusted to keep the TSH slightly suppressed, so the risk of TSH-stimulated growth of the nodule is reduced. For patients under age 40 years and for healthier older patients, surgery is usually recommended; patients are made euthyroid with a thiourea preoperatively and given several days of iodine, ipodate sodium, or iopanoic acid before surgery as in Graves disease (see above). Transient postoperative hypothyroidism resolves spontaneously. Permanent hypothyroidism occurs in about 14% of patients by 6 years after surgery. Patients with a toxic solitary nodule who are over age 40 years or in poor health may be offered 131I therapy. If the patient has been receiving methimazole preparatory to 131I, the TSH should be kept slightly suppressed in order to reduce the uptake of 131I by the normal thyroid. Nevertheless, permanent hypothyroidism occurs in about one-third of patients after 8 years of 131I therapy. The nodule remains palpable in 50% and may grow in 10% of patients after 131I.

### C. Toxic Multinodular Goiter

Hyperthyroidism caused by a toxic multinodular goiter may also be treated with propranolol ER and methimazole, as in Graves disease. Methimazole does reverse hyperthyroidism, but there is a 95% recurrence rate if it is stopped. Definitive treatment for large multinodular goiters is surgery, prior to which patients are rendered euthyroid. Surgery is particularly indicated to relieve pressure symptoms or for cosmetic indications. Patients with toxic multinodular goiter are prepared for surgery the same as those with Graves disease. Patients who are to receive 131I treatment are rendered nearly euthyroid with methimazole, which is stopped at least 4 days before RAI treatment. Meanwhile, the patient follows a low-iodine diet; this is done to enhance the thyroid gland’s uptake of RAI, which may be relatively low in this condition (compared to Graves disease). Relative high doses of 131I are usually required; recurrent thyrotoxicosis and hypothyroidism are common, so patients must be monitored closely. Peculiarly, in about 5% of patients with diffusely nodular toxic goiter, the administration of 131I therapy may induce Graves disease. Also, Graves eye disease has occurred rarely following 131I therapy for multinodular goiter.
D. Subacute (de Quervain) Thyroiditis

Patients with hyperthyroidism due to subacute thyroiditis are treated symptomatically with oral propranolol ER at initial doses of about 60–80 mg twice daily and increased every 2–3 days until the heart rate is < 90 beats per minute. Iopodate sodium or ipanoic acid, 500 mg orally daily, promptly corrects elevated T₄ levels and is continued for 15–60 days until the serum FT₄ level normalizes. The condition subsides spontaneously within weeks to months. Thioureas are ineffective, since thyroid hormone production is actually low in this condition. RAI is ineffective, since the thyroid’s iodine uptake is low. Since periods of hypothyroidism may occur following the initial inflammatory episode, patients should have close clinical follow-up, with serum FT₄ measurement when necessary. Prompt treatment of the transient hypothyroidism may reduce the incidence of recurrent thyroiditis. Pain can usually be managed with non-aspirin nonsteroidal anti-inflammatory drugs.

E. Hashimoto Thyroiditis (Hashitoxicosis)

Rarely, hyperthyroidism develops as a result of release of stored thyroid hormone during severe Hashimoto thyroiditis. Serum thyroperoxidase or thyroglobulin antibodies are usually high, but RAI uptake is low, thus distinguishing it from Graves disease. This is especially common in postpartum women, in whom it may be transient. Treatment is with propranolol ER. Iopodate sodium or ipanoic acid may also be used as described above. Patients are monitored carefully for the development of hypothyroidism and treated.

F. Hyperthyroidism during Pregnancy and Lactation

There may be a slightly increased risk of fetal anomalies associated with methimazole in the first trimester. Therefore, pregnant women with hyperthyroidism are treated with propylthiouracil in the first trimester and then may be switched to methimazole. Either thiourea should be given in the smallest dose possible, permitting mild subclinical hyperthyroidism to occur since it is usually well tolerated. Both propylthiouracil and methimazole cross the placenta and can induce hypothyroidism, with fetal TSH hypersecretion and goiter. Thyroid hormone administration to the mother does not prevent hyperthyroidism in the fetus, since T₄ and T₃ do not freely cross the placenta. Fetal hyperthyroidism is rare if the mother’s hyperthyroidism is controlled with small daily doses of propylthiouracil (50–150 mg/d orally) or methimazole (5–15 mg/d orally). Thyroidectomy is reserved for women who are allergic or resistant to antithyroid drugs (usually due to noncompliance) or who have very large goiters. Fetal ultrasound at 32 weeks gestation can visualize any fetal goiter, so fetal thyroid dysfunction can be diagnosed and treated. Both methimazole and propylthiouracil are secreted in breast milk, but not in amounts that affect the infant’s thyroid hormone levels. No adverse reactions to these drugs (eg, rash, hepatic dysfunction, leukopenia) have been reported in breast-fed infants. Recommended doses are 20 mg orally daily or less for methimazole and 450 mg orally daily or less for propylthiouracil. It is recommended that the medication be taken just after breast-feeding.

G. Treatment of Other Causes of Hyperthyroidism

Patients with thyrotoxicosis from thyrotrope pituitary hyperplasia are treated with propranolol ER as described above. Definitive treatment is with RAI or thyroid surgery. Patients with thyrotoxicosis caused by a thyrotrope pituitary adenoma are treated with propranolol ER and methimazole, followed by transsphenoidal resection of the pituitary tumor, when possible. Patients with type 1 amiodarone-induced thyrotoxicosis usually require propranolol ER. Therapy with ¹³¹I may be successful in some patients with sufficient RAI uptake. If radioiodine therapy is not an option (due to insufficient RAI uptake), treatment with methimazole is begun. If radioiodine is administered, methimazole may be started several days afterward. After two doses of methimazole, ipanoic acid or sodium iopodate may be added to the regimen to further block conversion of T₄ to T₃; the recommended dosage for each is 500 mg orally twice daily for 3 days, followed by 500 mg once daily until thyrotoxicosis is resolved. If ipanoic acid or sodium iopodate is not available, the alternative is potassium perchlorate; it is given in doses of ≤ 1000 mg daily (in divided doses) for a course not to exceed 30 days in order to avoid the complication of aplastic anemia. Amiodarone may be withdrawn but this does not have a significant therapeutic effect for several months. Thyroidectomy is reserved for resistant cases.

Patients with type 2 amiodarone-induced thyrotoxicosis usually require propranolol ER. Prednisone is given at an initial dose of about 0.5–0.7 mg/kg; that dose of prednisone is continued for about 2 weeks and then slowly tapered and finally withdrawn after about 3 months. Iopanoic acid or ipodate sodium may also be used (see above). Withdrawal of amiodarone is not usually necessary. Methimazole is ineffective. Thyroidectomy is rarely required, since the condition is transient. Most patients become euthyroid within 30–40 days, except in cases of very severe thyrotoxicosis.

Some cases of amiodarone-induced thyrotoxicosis cannot be strictly categorized as either type 1 or type 2. Such patients usually have negligible radioiodine uptake, so treatment is usually commenced with propranolol ER and a 1-month trial of methimazole. Iopanoic acid or ipodate sodium can be added to methimazole as noted above. Prednisone is given for severe thyrotoxicosis or when methimazole fails to correct the thyrotoxicosis. Amiodarone is discontinued, when feasible.

H. Treatment of Complications

1. Graves ophthalmopathy—The risk of having a “flare” of ophthalmopathy following ¹³¹I treatment for hyperthyroidism is about 6% for nonsmokers and 23% for smokers. Graves ophthalmopathy can also be aggravated by thiazolidinediones (eg, pioglitazone, rosiglitazone); these oral diabetic agents should be avoided or withdrawn in patients with Graves disease. Patients with mild ophthalmopathy
may be treated with selenium 100 mcg orally twice daily, which slows the progression of the disease. For acute, progressive exophthalmos, intravenous methylprednisolone, begun promptly, is superior to oral prednisone, possibly due to improved compliance. Methylprednisolone is given intravenously, 500 mg weekly for 6 weeks, then 250 mg weekly for 6 weeks. If oral prednisone is chosen for treatment, it must be given promptly in daily doses of 40–60 mg/d orally, with dosage reduction over several weeks. Higher initial prednisone doses of 80–120 mg/d are used when there is optic nerve compression. Prednisone alleviates acute eye symptoms in 64% of nonsmokers, but only 14% of smokers respond well.

Progressive active exophthalmos may be treated with retrobulbar radiation therapy using a supervoltage linear accelerator (4–6 MeV) to deliver 20 Gy over 2 weeks to the extraocular muscles, avoiding the cornea and lens. Prednisone in high doses is given concurrently. Patients who respond well to orbital radiation include those with signs of acute inflammation, recent exophthalmos (< 6 months), or optic nerve compression. Patients with chronic proptosis and orbital muscle restriction respond less well. Retrobulbar radiation does not cause cataracts or tumors; however, it can cause radiation-induced retinopathy (usually subclinical) in about 5% of patients overall, mostly in diabetics. For severe cases, orbital decompression surgery may save vision, though diplopia often persists postoperatively. General eye protective measures include wearing glasses to protect the protruding eye and taping the lids shut during sleep if corneal drying is a problem. Methylcellulose drops and gels (“artificial tears”) may also help. Tarsorrhaphy or canthoplasty can frequently help protect the cornea and provide improved appearance. Hypothyroidism and hyperthyroidism must be treated promptly.

2. Cardiac complications—

A. Sinus tachycardia—Treatment consists of treating the thyrotoxicosis. A β-blocker (as described above) such as propranolol is used in the interim unless there is an associated cardiomyopathy.

B. Atrial fibrillation—Hyperthyroidism must be treated immediately (see above). Other drugs, including digoxin, β-blockers, anticoagulants, may be required. Electrical cardioversion is unlikely to convert atrial fibrillation to normal sinus rhythm while the patient is thyrotoxic. Spontaneous conversion to normal sinus rhythm occurs in 62% of patients with return of euthyroidism, but that likelihood decreases with age. Following conversion to euthyroidism, there is a 60% chance that atrial fibrillation will recur, despite normal thyroid function tests. Those with persistent atrial fibrillation may have elective cardioversion 4 months after resolution of hyperthyroidism.

(1) Digoxin—Digoxin is used to slow a fast ventricular response to thyrotoxic atrial fibrillation; it must be used in larger than normal doses because of increased clearance and an increased number of cardiac cellular sodium pumps requiring inhibition. Digoxin doses are reduced as hyperthyroidism is corrected.

(2) β-Blockers—β-Blockers may also reduce the ventricular rate, but they must be used with caution—particularly in patients with cardiomegaly or signs of heart failure—since their negative inotropic effect may precipitate congestive heart failure. Therefore, an initial trial of a short-duration β-blocker should be considered, such as esmolol intravenously. If a β-blocker is used, doses of digoxin must be reduced.

(3) Anticoagulants—Anticoagulation is indicated in the following situations: left atrial enlargement on echocardiogram, global left ventricular dysfunction, recent congestive heart failure, hypertension, recurrent atrial fibrillation, or a history of previous thromboembolism. The doses of warfarin required in thyrotoxicosis are smaller than normal because of an accelerated plasma clearance of vitamin K–dependent clotting factors. Higher warfarin doses are usually required as hyperthyroidism subsides.

C. Heart failure—Heart failure due to thyrotoxicosis may be caused by extreme tachycardia, cardiomyopathy, or both. Very aggressive treatment of the hyperthyroidism is required in either case (see Thyroid Crisis, below). The tachycardia from atrial fibrillation is treated with digoxin as above. Intravenous furosemide is typically required. Oral spironolactone or eplerenone may be helpful. If tachycardia appears to be the main cause of the failure, β-blockers are administered cautiously as described above.

Congestive heart failure may occur as a result of low-output dilated cardiomyopathy in the setting of hyperthyroidism. It is uncommon and may be caused by an idiosyncratic severe toxic effect of hyperthyroidism upon certain hearts. Cardiomyopathy may occur at any age and without preexisting cardiac disease. β-Blockers and calcium channel blockers are avoided. Emergency treatment may include afterload reduction, diuretics, digoxin, and other inotropic agents while the patient is being rendered euthyroid. Heart failure usually persists despite correction of hyperthyroidism.

D. Apathetic hyperthyroidism—Apathetic hyperthyroidism may present with angina pectoris. Treatment is directed at reversing the hyperthyroidism as well as providing standard antianginal therapy. Coronary angioplasty or bypass grafting can often be avoided by prompt diagnosis and treatment.

3. Thyroid crisis or “storm”—This disorder, rarely seen today, is an extreme form of thyrotoxicosis that may be triggered by stressful illness, thyroid surgery, or RAI administration. Its manifestations often include marked delirium, severe tachycardia, vomiting, diarrhea, dehydration and very high fever. The mortality rate is high.

A threeurlura drug is given (eg, methimazole, 15–25 mg orally every 6 hours or propylthiouracil, 150–250 mg orally every 6 hours). Ipudate sodium (500 mg/d orally) can be helpful if begun 1 hour after the first dose of thiourea. Iodide is given 1 hour later as Lugol solution (10 drops three times daily orally) or as sodium iodide (1 g intravenously slowly). Propranolol is given (cautiously in the presence of heart failure; see above) in a dosage of 0.5–2 mg intravenously every 4 hours or 20–120 mg orally every 6 hours. Hydrocortisone is usually given in doses of 50 mg orally every 6 hours, with rapid dosage reduction as the clinical situation improves. Aspirin is avoided since it
displaces T₄ from TBG, raising FT₄ serum levels. Definitive treatment with ¹³¹I or surgery is delayed until the patient is euthyroid.

4. Hyperthyroidism from postpartum thyroiditis—Propranolol ER is given during the hyperthyroid phase followed by levothyroxine during the hypothyroidism phase (see Thyroiditis, below).

5. Graves dermopathy—Treatment involves application of a topical corticosteroid (eg, fluocinolone) with nocturnal plastic occlusive dressings.

6. Thyrotoxic hypokalemic periodic paralysis—Sudden symmetric flaccid paralysis, along with hypokalemia and hypophosphatemia can occur with hyperthyroidism. There are often few classic signs of thyrotoxicosis. It is most prevalent in Asian and Native Americans with hyperthyroidism and is 30 times more common in men than women.

Therapy with oral propranolol, 3 mg/kg, normalizes the paralysis within 2–3 hours. No intravenous potassium or phosphate is ordinarily required. Intravenous dextrose and oral carbohydrate aggravate the condition and are to be avoided. Therapy is continued with propranolol, 60–80 mg orally every 8 hours (or sustained-action propranolol ER daily at equivalent daily dosage), along with a thiourea drug such as methimazole to treat the hyperthyroidism.

-Prognosis-

Graves disease may rarely subside spontaneously, particularly when it is mild or subclinical. Graves disease that presents in early pregnancy has a 30% chance of spontaneous remission before the third trimester. The ocular, cardiac, and psychological complications can become serious and persistent even after treatment. Permanent hypoparathyroidism and vocal cord palsy are risks of surgical thyroidectomy. Recurrences are common following thyroidectomy therapy but also occur after low-dose ¹³¹I therapy or subtotal thyroidectomy. With adequate treatment and long-term follow-up, the results are usually good. However, despite treatment for their hyperthyroidism, women experience an increased long-term risk of death from thyroid disease, cardiovascular disease, stroke, and fracture of the femur. Posttreatment hyperthyroidism is common. It may occur within a few months or up to several years after RAI therapy or subtotal thyroidectomy. Malignant exophthalmos has a poor prognosis unless treated aggressively.

Subclinical hyperthyroidism refers to a condition in which asymptomatic individuals have a low serum TSH and normal FT₃ and FT₄. Most such patients do well without treatment. In one series, clinical hyperthyroidism developed in only one of seven patients after 2 years. In most patients, the serum TSH may revert to normal within 2 years. Most such patients do not have accelerated bone loss. However, if a baseline bone density shows significant osteopenia, bone densitometry may be performed periodically. In persons over age 60 years, serum TSH is very low (< 0.1 mU/L) in 3% and mildly low (0.1–0.4 mU/L) in 9%. The chance of developing atrial fibrillation is 2.8% yearly in elderly patients with very low TSH and 1.1% yearly in those with mildly low TSH. Asymptomatic persons with very low TSH are monitored closely but are not treated unless atrial fibrillation or other manifestations of hyperthyroidism develop.

Thyroiditis may be classified as follows: (1) chronic lymphocytic thyroiditis due to autoimmunity (also called Hashimoto thyroiditis), (2) subacute thyroiditis, (3) suppurrative thyroiditis, and (4) Riedel thyroiditis.

Hashimoto thyroiditis is an autoimmune condition and the most common thyroid disorder in the United States. B-lymphocytes invade the thyroid gland, such that the condition is also known as chronic lymphocytic thyroiditis. Detectable levels of antithyroid antibodies are usually present: antithyroglobulin antibodies or antithyroglobulin antibodies, or both. Elevated serum levels of antithyroid antibodies are found in 3% of men and 13% of women. Women over the age of 60 years have a 25%
Hashimoto thyroiditis tends to be familial and is six times more common in women than in men. Its frequency is increased by dietary iodine supplementation. Certain drugs (amiodarone, interferon-α, interferon-β, interleukin-2, G-CSF) frequently induce thyroid autoantibodies. Childhood or occupational exposure to head–neck external beam radiation increases the lifetime risk of Hashimoto thyroiditis. Subclinical thyroiditis is extremely common, as evidenced in autopsy series that have found focal thyroiditis in about 40% of women and 20% of men. Hashimoto thyroiditis often progresses to hypothyroidism, which may be linked to thyrotrpin receptor–blocking antibodies, detected in 10% of patients with Hashimoto thyroiditis. Hypothyroidism is more likely to develop in smokers than in nonsmokers, possibly due to the thiocyanates in cigarette smoke. High serum levels of thyroid peroxidase antibody also predict progression from subclinical hypothyroidism to symptomatic hypothyroidism. Although the hypothyroidism is usually permanent, up to 11% of patients experience a remission after several years. There are two possible causes for such remissions: (1) the Hashimoto thyroiditis may improve spontaneously; and (2) thyroid-stimulating immunoglobulin is produced in sufficient quantities to overwhelm the destructive effects of concurrent Hashimoto thyroiditis, causing the thyroid to produce more thyroid hormone. Rarely, if the thyroid gland goes on to produce excessive thyroid hormone, the result is an autoimmune hyperthyroidism (see Graves disease).

Hashimoto thyroiditis is sometimes associated with other endocrine deficiencies as part of polyglandular autoimmunity (PGA). Adults with type 2 PGA are prone to autoimmune thyroiditis, diabetes mellitus type 1, autoimmune gonadal failure, hypoparathyroidism, and adrenal insufficiency (see Adrenal Insufficiency). Thyroiditis is associated with other autoimmune conditions, such as pernicious anemia, Sjögren syndrome, vitiligo, inflammatory bowel disease, and celiac disease. The incidence of celiac disease in patients with Hashimoto thyroiditis is about 5%. Hashimoto thyroiditis is very rarely associated with other autoimmune conditions such as myocarditis, hypophysitis, alopecia areata, encephalitis, primary pulmonary hypertension, or membranous nephropathy. Women with gonadal dysgenesis (Turner syndrome) have a 15% incidence of significant thyroid dysfunction by age 40 years. Thyroiditis is also commonly seen in patients with hepatitis C.

Painless postpartum thyroiditis refers to autoimmune thyroiditis that occurs soon after delivery in 7.2% of women. There is some evidence that the autoimmunity may be triggered by the accumulation of fetal cells in the maternal thyroid during pregnancy, a condition known as microchimerism. Women in whom postpartum thyroiditis develops have a 70% chance of recurrence after subsequent pregnancies. It occurs most commonly in women who have high levels of thyroid peroxidase antibody in the first trimester of pregnancy or immediately after delivery. It is also more common in women with other autoimmunity or a family history of Hashimoto thyroiditis.

Painless sporadic thyroiditis is thought to be a subacute form of Hashimoto thyroiditis that is similar to painless postpartum thyroiditis (see above), except that it is not related to pregnancy. It accounts for about 1% of cases of thyrotoxicosis.

Subacute thyroiditis—also called de Quervain thyroiditis, granulomatous thyroiditis, and giant cell thyroiditis—is relatively common. It is believed to be caused by a viral infection and often follows an upper respiratory tract infection. Its incidence peaks in the summer. It accounts for up to 5% of clinical thyroid disease and young and middle-aged women are most commonly affected.

Suppurative thyroiditis refers to a nonviral infection of the thyroid gland. It is usually bacterial. However, mycobacterial, fungal, and parasitic infections can occur, particularly in immunosuppressed individuals. Suppurative thyroiditis is quite rare, since the thyroid is resistant to infection, largely due to its high iodine content. It tends to affect patients with preexistent thyroid disease. Congenital pyriform sinus fistulas are a cause for recurrent suppurative thyroiditis in otherwise normal individuals.

Riedel thyroiditis is also called invasive fibrous thyroiditis, Riedel struma, woody thyroiditis, ligneous thyroiditis, and invasive thyroiditis. It is the rarest form of thyroiditis and is found most frequently in middle-aged or elderly women. It is usually a manifestation of a multifocal systemic fibrosis syndrome.

**Clinical Findings**

**A. Symptoms and Signs**

In Hashimoto thyroiditis, the thyroid gland is usually diffusely enlarged, firm, and finely nodular. One thyroid lobe may be asymmetrically enlarged, raising concerns about neoplasm. Although patients may complain of neck tightness, pain and tenderness are not usually present. About 10% of cases are atrophic, the gland being fibrotic, particularly in elderly women.

Systemic manifestations are mostly related to ambient levels of thyroid hormone. However, depression and chronic fatigue are more common in such patients, even after correction of hypothyroidism. About one-third of patients have mild dry mouth (xerostomia) or dry eyes (keratoconjunctivitis sicca) of an autoimmune nature related to Sjögren syndrome. It may be associated with myasthenia gravis, which is usually of mild severity, mainly affecting the extraocular muscles and having a relatively low incidence of detectable AChR Ab or thymic disease. Associated celiac disease can produce fatigue or depression, often in the absence of gastrointestinal symptoms.

Postpartum thyroiditis is typically manifested by hyperthyroidism that begins 1–6 months after delivery and persists for only 1–2 months. Then, hypothyroidism tends to develop in affected women beginning 4–8 months after delivery.
Thyrotoxic symptoms in painful sporadic thyroiditis are usually mild; a small, nontender goiter may be palpated in about 50% of such patients. High serum thyroid peroxidase antibody concentrations are found in only 50% of such patients. The course is similar to painless postpartum thyroiditis.

Subacute thyroiditis presents with an acute, usually painful enlargement of the thyroid gland, often with dysphagia. The pain may radiate to the ears. Patients usually have a low-grade fever and fatigue. The manifestations may persist for weeks or months and may be associated with malaise. If there is no pain, it is called silent thyroiditis. Thyrotoxicosis develops in 50% of affected patients and tends to last for several weeks. Subsequently, hypothyroidism develops that lasts 4–6 months. Normal thyroid function typically returns within 12 months, but persistent hypothyroidism develops in 5% of patients.

Patients with suppurative thyroiditis usually are febrile and have severe pain, tenderness, redness, and fluctuation in the region of the thyroid gland. In Riedel thyroiditis, thyroid enlargement is often asymmetric; the gland is stony hard and adherent to the neck structures, causing signs of compression and invasion, including dysphagia, dyspnea, pain, and hoarseness. Related conditions include retroperitoneal fibrosis, fibrosing mediastinitis, sclerosing cervicitis, subretinal fibrosis, and biliary tract sclerosis. It may respond to therapy with tamoxifen (see Treatment).

**B. Laboratory Findings**

In Hashimoto thyroiditis with clinically evident disease, there are usually increased circulating levels of antithyroid peroxidase (90%) or antithyroglobulin (40%) antibodies. Antithyroid antibodies decline during pregnancy and are often undetectable in the third trimester. Once Hashimoto thyroiditis has been diagnosed, monitoring of these antibody levels is not necessary. The serum TSH level is elevated if thyroid hormone is not elaborated in adequate amounts by the thyroid gland.

Patients with Hashimoto thyroiditis have a 15% incidence of having serum antibodies associated with celiac disease (sprue, gluten-sensitive enteropathy). At least 5% of patients with Hashimoto thyroiditis are found to have clinically significant celiac disease. Although most patients with celiac disease have gastrointestinal complaints such as bloating or diarrhea, vague symptoms such as fatigue or ennuï may predominate. Serum levels of IgA endomysial antibody or IgA tissue transglutaminase (tTG) antibody may be elevated. However, these antibody levels decline on a low gluten diet. Many patients with mild celiac disease have negative serology and a trial of a gluten-free diet is the most sensitive test.

In subacute thyroiditis, the ESR is markedly elevated while antithyroid antibody titers are low, distinguishing it from autoimmune thyroiditis. In suppurative thyroiditis, both the leukocyte count and ESR are usually elevated.

With hyperthyroidism due to Hashimoto thyroiditis or subacute thyroiditis, serum FT₄ levels tend to be proportionally higher than T₃ levels, since the hyperthyroidism is due to the passive release of stored thyroid hormone, which is predominantly T₃; this is in contrast to Graves disease and toxic nodular goiter, where T₃ is relatively more elevated. Because T₃ is less active than T₄, the hyperthyroidism seen in thyroiditis is usually less severe. Serum levels of TSH are suppressed in hyperthyroidism due to thyroiditis.

**C. Imaging**

Ultrasound in cases of Hashimoto thyroiditis typically shows a gland with characteristic diffuse heterogeneous density and hypoechogenicity. Ultrasonography of the thyroid helps distinguish thyroiditis from multinodular goiter or thyroid nodules that are suspicious for malignancy. It is also helpful in guiding FNA biopsy of small suspicious thyroid nodules. Color-flow Doppler ultrasonography can help distinguish thyroiditis from Graves disease, since patients with Graves disease have a hypervascular thyroid gland, whereas in thyroiditis there is normal or reduced vascularity.

RAI uptake and scan may be helpful in determining the cause of hyperthyroidism, distinguishing thyroiditis from Graves disease, since patients with subacute thyroiditis exhibit a very low RAI uptake. In patients with chronic Hashimoto thyroiditis (euthyroid or hypothyroid), RAI uptake may be normal or high with uneven uptake on the scan; scanning is not useful in making the diagnosis.

[¹⁸F]Fluorodeoxyglucose positron emission tomography (¹⁸FDG-PET) scanning frequently shows diffuse thyroid uptake of isotope in cases of thyroiditis. About 3% of all ¹⁸FDG-PET scans shows such uptake. However, discrete thyroid nodules can also be discovered on ¹⁸FDG-PET scanning and are known as "thyroid PET incidentalomas," of which 50% are malignant.

**D. Fine-Needle Aspiration Biopsy**

Patients with Hashimoto thyroiditis who have a thyroid nodule should have an ultrasound-guided FNA biopsy, since the risk of papillary thyroid cancer is about 8% in such nodules. When suppurative thyroiditis is suspected, an FNA biopsy with Gram stain and culture is required. FNA biopsy is usually not required for subacute thyroiditis but shows characteristic giant multinucleated cells.

**Complications**

Hashimoto thyroiditis may lead to hypothyroidism or transient thyrotoxicosis. Perimenopausal women with high serum levels of antithyroid peroxidase antibodies have a higher relative risk of depression independently of ambient thyroid hormone levels.

Pregnant women with Hashimoto thyroiditis have an increased risk of spontaneous miscarriage in the first trimester of pregnancy. Hyperthyroidism may develop in patients with Hashimoto thyroiditis, either due to the emergence of Graves disease or due to the release of stored thyroid hormone, which is caused by inflammation. The latter condition has variably been termed “hashitoxicosis” or “painless sporadic thyroiditis,” it is known as postpartum painless thyroiditis when it occurs in women after delivery.

Patients with Hashimoto thyroiditis have an increased risk of other autoimmune conditions, such as Addison disease, hypoparathyroidism, diabetes, pernicious anemia, biliary cirrhosis, vitiligo, and celiac disease.
In the suppurative forms of thyroiditis, any of the complications of infection may occur; the subacute and chronic forms of the disease are complicated by the effects of pressure on the neck structures: dyspnea and, in Riedel struma, vocal cord palsy. Papillary thyroid carcinoma or thyroid lymphoma may rarely be associated with chronic thyroiditis and must be considered in the diagnosis of uneven painless enlargements that continue in spite of treatment; such patients require FNA biopsy.

### Differential Diagnosis

Thyroiditis must be considered in the differential diagnosis of all types of goiters, especially if enlargement is rapid. The very low RAI uptake in subacute thyroiditis with elevated T4 and T3 is helpful. Thyroid autoantibody tests have been of help in the diagnosis of Hashimoto thyroiditis, but the tests are not specific and may also be positive in patients with multinodular goiters, malignancy (eg, thyroid carcinoma, lymphoma), and concurrent Graves disease. The subacute and suppurative forms of thyroiditis may resemble any infectious process in or near the neck structures. Chronic thyroiditis, especially if the enlargement is uneven and if there is pressure on surrounding structures, may resemble carcinoma, and both disorders may be present in the same gland.

### Treatment

#### A. Hashimoto Thyroiditis

If hypothyroidism is present, levothyroxine should be given in the usual replacement doses (0.05–0.2 mg orally daily). In patients with a large goiter and normal or elevated serum TSH, an attempt is made to shrink the goiter by administering levothyroxine in doses sufficient to drive the serum TSH below the reference range while maintaining clinical euthyroidism. Suppressive doses of T4 tend to shrink the goiter an average of 30% over 6 months. If the goiter does not regress, lower replacement doses of levothyroxine may be given. If the thyroid gland is only minimally enlarged and the patient is euthyroid, regular observation is in order, since hypothyroidism may develop subsequently—often years later. (See Hypothyroidism section.)

In one study involving 21 patients with Hashimoto thyroiditis and subclinical hypothyroidism, simvastatin (20 mg orally daily) improved thyroid function over 8 weeks, possibly by stimulating apoptosis of certain types of lymphocytes. In another study, selenium (200 mcg daily orally for 3 months) reduced the serum levels of antithyperoxidase antibodies by 49% versus a 10% reduction in the placebo arm. The long-term effectiveness of simvastatin or selenium therapy on the course of Hashimoto thyroiditis is unknown.

#### B. Subacute Thyroiditis

All treatment is empiric and must be continued for several weeks. Recurrence is common. The drug of choice is aspirin, which relieves pain and inflammation. Thyrotoxic symptoms are treated with propranolol, 10–40 mg every 6 hours. Iodinated contrast agents cause a prompt fall in serum T4 levels and a dramatic improvement in thyrotoxic symptoms. Sodium ipodate (Oragrafin, Bilivist) or iopanoic acid (Telepaque) is given orally in doses of 500 mg orally daily until serum FT4 levels return to normal. Transient hypothyroidism is treated with T4 (0.05–0.1 mg orally daily) if symptomatic.

#### C. Suppurative Thyroiditis

Treatment is with antibiotics and with surgical drainage when fluctuation is marked.

#### D. Riedel Struma

The treatment of choice is tamoxifen, 20 mg orally twice daily, which must be continued for years. Tamoxifen can induce partial to complete remissions in most patients within 3–6 months. Its mode of action appears to be unrelated to its antiestrogen activity. Short-term corticosteroid treatment may be added for partial alleviation of pain and compression symptoms. Surgical decompression usually fails to permanently alleviate compression symptoms; such surgery is difficult due to dense fibrous adhesions, making surgical complications more likely.

### Prognosis

Hashimoto thyroiditis is occasionally associated with other autoimmune disorders (diabetes mellitus, Addison disease, pernicious anemia, etc.). In general, however, patients with Hashimoto thyroiditis have an excellent prognosis, since the condition either remains stable for years or progresses slowly to hypothyroidism, which is easily treated. Although 80% of women with postpartum thyroiditis subsequently recover normal thyroid function, permanent hypothyroidism eventually develops in about 50% within 7 years. Permanent hypothyroidism is more common in women who are multiparous or who have had a spontaneous abortion. In subacute thyroiditis, spontaneous remissions and exacerbations are common; the disease process may smolder for months. Papillary thyroid carcinoma carries a relatively good prognosis when it occurs in patients with Hashimoto thyroiditis.

THYROID NODULES & MULTINODULAR GOITER

ESSENTIALS OF DIAGNOSIS

▶ Single or multiple thyroid nodules are commonly found with careful thyroid examinations.
▶ Thyroid function tests mandatory.
▶ Thyroid biopsy for single or dominant nodules or for a history of prior head-neck or chest-shoulder radiation.
▶ Ultrasound examination useful for biopsy and follow-up.
▶ Clinical follow-up required.

General Considerations

Thyroid nodules are extremely common. In Germany, neck ultrasound screening of adults found a 20% incidence of thyroid nodules >1 cm in diameter. Palpable nodules are found in 5% of women and 1% of men in iodine-sufficient areas of the world. Palpable thyroid nodules are even more common in iodine-deficient geographic areas (see Iodine Deficiency Disorder & Endemic Goiter). Each year in the United States, about 275,000 thyroid nodules are detected by palpation, of which 10% are malignant. Palpable thyroid nodules are increasingly prevalent with age. On high-resolution thyroid ultrasound, about 50% of palpable "solitary nodules" are found to be just one nodule in a multinodular goiter.

In recent years, an increased general use of scanning (CT, MRI, ultrasound, PET) has led to an increased rate of incidentally detecting nonpalpable thyroid nodules. In fact, thyroid ultrasound detects thyroid nodules in about 20% of randomly screened healthy adults.

Although 90% of thyroid nodules are benign, the presence of a thyroid nodule ≥1 cm diameter warrants follow-up and further testing for function and malignancy. An occasional nodule <1 cm diameter requires follow-up if it has high-risk characteristics on ultrasound or if the patient has had prior head-neck radiation therapy. Thyroid nodules that are incidentally discovered on 18FDG-PET scanning have a 33% risk for being malignant and definitely require biopsy.

Most patients with a thyroid nodule are euthyroid, but there is a high incidence of hypothyroidism or hyperthyroidism. Goiter may be caused by numerous conditions, including multinodular goiter, iodine deficiency, pregnancy (in areas of iodine deficiency), Graves disease, Hashimoto thyroiditis, subacute thyroiditis, or infections. About 90% of thyroid nodules are benign adenoma, colloid nodule, or cyst but may sometimes be a primary thyroid malignancy or (less frequently) a metastatic neoplasm. Patients with multiple thyroid nodules have the same overall risk of thyroid cancer as patients with solitary nodules. The risk of a thyroid nodule being malignant is higher among patients with a history of head–neck radiation, total body radiation for bone marrow transplantation, exposure to radioactive fallout as a child or teen, a family history of thyroid cancer or a thyroid cancer syndrome (eg, Cowden syndrome, multiple endocrine neoplasia type 2, familial polyposis, Carney syndrome), or a personal history of another malignancy. The risk of malignancy is also higher if there is hoarseness or vocal fold paralysis, and if the thyroid nodule is large, adherent to the trachea or strap muscles, or associated with lymphadenopathy. The presence of Hashimoto thyroiditis does not reduce the risk of malignancy; a nodule of ≥1 cm in a gland with thyroiditis carries an 8% chance of malignancy.

Clinical Findings

Table 26–6 illustrates the approach to the evaluation of thyroid nodules based on the index of suspicion for malignancy.

A. Symptoms and Signs

Most small thyroid nodules cause no symptoms. They may sometimes be detected only by having the patient swallow during careful inspection and palpation of the thyroid.

A thyroid nodule or multinodular goiter can grow to become visible and of concern to the patient. Particularly large nodular goiters can become a cosmetic embarrassment. Nodules can grow large enough to cause discomfort, hoarseness, or dysphagia. Retrosternal large multinodular goiters can cause dyspnea due to tracheal compression. Large substernal goiters may cause superior vena cava syndrome, manifested by facial edema and jugular vein distention that progress to cyanosis and facial edema when both arms are kept raised over the head (Pemberton sign).

Depending on their cause, goiters and thyroid nodules may be associated with hypothyroidism (Hashimoto thyroiditis, endemic goiter) or hyperthyroidism (Graves disease, toxic nodular goiter, subacute thyroiditis, and thyroid cancer with metastases).

B. Laboratory Findings

A serum TSH level (sensitive assay) should be obtained for all patients with a thyroid nodule. Patients with a subnormal serum TSH must have further assessment for hyperthyroidism and have a radionuclide thyroid scan (123I or 99mTc pertechnetate) to determine whether the nodule is hyperfunctioning; hyperfunctioning nodules are rarely malignant. Tests for antithyroid peroxidase antibodies and antithyroglobulin antibodies may also be helpful. Very high antibody levels are found in Hashimoto thyroiditis. However, thyroiditis frequently coexists with malignancy, so suspicious nodules should always be biopsied. Serum calcitonin is obtained if a medullary thyroid carcinoma is suspected in a family member with a history of familial medullary thyroid carcinoma or MEN type 2.

C. Imaging

Neck ultrasonography should be performed to measure the size of a nodule and to determine whether a palpable nodule is part of a multinodular goiter. The following ultrasound characteristics of thyroid nodules increase the
E. Fine-Needle Aspiration Biopsy

Fine-needle aspiration (FNA) biopsy is the best method to assess a thyroid nodule for malignancy. FNA biopsy can be done while patients continue taking anticoagulants or aspirin. For multinodular goiters, the four largest nodules (≥ 1 cm diameter) should be biopsied to minimize the risk of missing a malignancy. For solitary thyroid nodules, FNA biopsy is indicated for the following: (1) nodules > 5 mm diameter with a suspicious appearance on ultrasound; (2) nodules associated with abnormal cervical lymph nodes; (3) nodules ≥ 1 cm diameter that are solid or have microcalcifications; (4) mixed cystic-solid nodules ≥ 1.5 cm diameter with any suspicious features on ultrasound or ≥ 2 cm diameter with benign features on ultrasound; (5) spongiform nodules ≥ 2 cm diameter. Pure cystic nodules are benign and do not require FNA biopsy.

Using ultrasound guidance for FNA biopsy improves the diagnostic accuracy for both palpable and nonpalpable thyroid nodules. The chance of an optimal tissue sampling is also improved by having an experienced clinician perform the FNA biopsy and by having the aspirate interpreted by a skilled cytopathologist.

D. Incidentally Discovered Thyroid Nodules

Thyroid nodules are frequently discovered as an incidental finding, with an incidence that depends on the imaging modality: MRI, 50%; CT, 13%; and 18FDG-PET, 2%. When such scanning detects a thyroid nodule, an ultrasound is performed to better determine the nodule’s risk for malignancy and the need for FNA biopsy, and to establish a baseline for ultrasound follow-up. The malignancy risk is about 17% for nodules discovered incidentally on CT or MRI, and 25–50% for nodules discovered incidentally by 18FDG-PET. For incidentally discovered thyroid nodules of borderline concern, follow-up thyroid ultrasound in 3–6 months may be helpful; growing lesions may be biopsied or resected.

E. Fine-Needle Aspiration Biopsy

Fine-needle aspiration (FNA) biopsy is the best method to assess a thyroid nodule for malignancy. FNA biopsy can be done while patients continue taking anticoagulants or aspirin. For multinodular goiters, the four largest nodules (≥ 1 cm diameter) should be biopsied to minimize the risk of missing a malignancy. For solitary thyroid nodules, FNA biopsy is indicated for the following: (1) nodules > 5 mm diameter with a suspicious appearance on ultrasound; (2) nodules associated with abnormal cervical lymph nodes; (3) nodules ≥ 1 cm diameter that are solid or have microcalcifications; (4) mixed cystic-solid nodules ≥ 1.5 cm diameter with any suspicious features on ultrasound or ≥ 2 cm diameter with benign features on ultrasound; (5) spongiform nodules ≥ 2 cm diameter. Pure cystic nodules are benign and do not require FNA biopsy.

Using ultrasound guidance for FNA biopsy improves the diagnostic accuracy for both palpable and nonpalpable thyroid nodules. The chance of an optimal tissue sampling is also improved by having an experienced clinician perform the FNA biopsy and by having the aspirate interpreted by a skilled cytopathologist.

In one review of thyroid FNA biopsies, about 70% were benign, 5% were malignant, 10% were “suspicious,” and 15% were “nondiagnostic.” Nondiagnostic, bloody, or hypocellular FNA biopsies should be repeated under ultrasound guidance; nodules that continue to have nondiagnostic cytology should be monitored closely; those that are solid or that grow should be resected.

When FNA cytology is “suspicious” for papillary thyroid carcinoma or Hurthle cell neoplasm, the risk of malignancy is 57%. When FNA cytology yields a “suspicious” follicular lesion, the overall risk of the lesion being malignant
is about 20–25%. The risk that a follicular lesion is malignant increases for patients who are much younger or older than age 50. Most patients with suspicious FNA cytology are advised to have surgery.

Cystic nodules yielding serous fluid are usually benign, but the aspirate should be submitted for cytologic testing. Cystic nodules yielding bloody fluid have a higher chance of being malignant.

False-positive thyroid FNA biopsy results occur at a rate of about 4%. False-negative thyroid FNA biopsy results also occur at an overall rate of about 4%, less commonly when performed under ultrasound guidance and interpreted by cytopathologists. False-negative results delay surgical excision and lead to an increased risk of vascular and capsular invasion by the malignancy. Some false-negative FNA biopsy results may not have actually been inaccurate, since truly benign thyroid nodules can later become malignant. Patients who have a negative thyroid FNA should have observational follow-up, ideally with both palpation and ultrasound; nodules that continue to grow should be rebiopsied or excised.

### Treatment

All thyroid nodules, including those that are benign, need to be monitored by regular periodic palpation and ultrasound and rebiopsied if growth occurs. A toxic multinodular goiter and hyperthyroidism, associated with the ingestion or intravenous administration of large amounts of iodine, may develop in patients with multinodular goiters. It is therefore prudent to minimize excessive dietary iodine intake and intravenous iodinated contrast. Patients found to have hyperthyroidism may have a RAI uptake and scan for additional evaluation, especially if \(^{131}I\) is a therapeutic consideration. Patients with toxic multinodular goiters may also be treated with methimazole, propranolol, or surgery (see Hyperthyroidism section).

#### A. Levothyroxine Suppression Therapy

Patients with elevated levels of serum TSH are treated with levothyroxine replacement. Otherwise, for small benign thyroid nodules, levothyroxine suppression therapy is not recommended. For larger nodules (> 2 cm), if TSH levels are elevated or normal, TSH suppression with levothyroxine (starting doses of 50 mcg orally daily) can be considered. Thyroxine suppression therapy is most successful in iodine-deficient areas of the world and less successful in iodine-sufficient regions. Long-term levothyroxine suppression of TSH tends to keep nodules from enlarging, but only 20% shrink more than 50%. In one 5-year study, thyroid nodule size increased in 29% of patients treated with levothyroxine, compared to growth in 56% of nodules in patients not receiving levothyroxine. Levothyroxine suppression also reduces the emergency of new nodules: 8% with levothyroxine and 29% without levothyroxine. Levothyroxine suppression therapy is not usually given to patients with cardiac disease, since it increases the risk for angina and atrial fibrillation. Levothyroxine suppression causes a small loss of bone density, particularly in postmenopausal women if the serum TSH is suppressed to < 0.05 mU/L. Such patients are advised to have bone density testing every 3–5 years. Levothyroxine should not be administered if the baseline TSH is low, since that is an indication of autonomous thyroid secretion, such that levothyroxine therapy will be ineffective and liable to cause clinical thyrotoxicosis.

Levothyroxine suppression needs to be carefully monitored, since it carries a 17% risk of inducing symptoms of hyperthyroidism. This can occur due to excessive levothyroxine dosing, the emergence of an autonomous or toxic nodule or Graves disease, or a reduction in thyroid binding globulin seen in early menopause or with discontinuing oral estrogen therapy. Therefore, coronary insufficiency and cardiac arrhythmias are relative contraindications to levothyroxine suppression. All patients receiving levothyroxine suppression therapy should have serum TSH levels monitored regularly, with the dose of levothyroxine adjusted to keep the serum TSH mildly suppressed between 0.2 mU/L and 0.8 mU/L. Thyroid nodules require careful clinical evaluation and thyroid palpation or ultrasound examinations about every 6 months initially. After several years of stability, yearly examinations are sufficient.

#### B. Potassium Iodide

Additional suppression of thyroid nodules may be obtained by adding oral potassium iodide, 150 mcg daily, to levothyroxine suppression therapy (see above) for patients with thyroid nodules ≥ 1 cm in diameter. In a German study, the addition of potassium iodide to levothyroxine further decreased thyroid nodule size over the course of 1 year. However, the study excluded children; pregnant women; non-whites; and patients with autoimmune thyroid disease, autonomous nodules, consumption of other iodine-containing medications, dermatitis herpetiformis, or iodine allergy. The long-term risk of administering potassium iodide to iodine-sufficient patients is unknown.

#### C. Surgery

Total thyroidectomy is required for thyroid nodules that are malignant on FNA biopsy (see Thyroid Cancer section). More limited thyroid surgery is indicated for benign nodules with indeterminate or suspicious cytologic test results, compression symptoms, discomfort, or cosmetic embarrassment. Surgery may also be used to remove hyperfunctioning “hot” thyroid adenomas or toxic multinodular goiter causing hyperthyroidism (see Hyperthyroidism section).

#### D. Percutaneous Ethanol Injection

Thyroid cysts can be aspirated, but cystic fluid recurs in 75% of patients. Percutaneous ethanol injection has been used to shrink pure cysts; it must often be repeated, but the success rate is 80%. Percutaneous ethanol injection can also be used to shrink benign (biopsy proven) thyroid nodules. The complication rate is about 9%, but serious or permanent complications are rare.

#### E. Radioiodine (\(^{131}I\)) Therapy

Radioactive \(^{131}I\) is a treatment option for hyperthyroid patients with toxic thyroid adenomas, multinodular goiter,
or Graves disease (see Hyperthyroidism section). It may also be used to shrink benign nontoxic thyroid nodules. Thyroid nodules shrink an average of 40% by 1 year and 59% by 2 years after 131I therapy. Nodules that shrink after 131I therapy generally remain palpable and become firmer; they may develop unusual cytologic characteristics on FNA biopsy. 131I therapy may be used to shrink large multinodular goiter but may rarely induce Graves disease. Hypothyroidism is a risk associated with thyroid nodules that prove to be malignant is determined by the histologic type and other factors (see below). Multinodular goiters tend to persist or grow slowly, even in iodine-deficient areas where iodine repletion usually does not shrink established goiters. Patients with very small, incidentally discovered, nonpalpable thyroid nodules do require follow-up with thyroid ultrasound every 1–2 years but are at low risk for malignancy. Nodules that are malignant have a minor effect on morbidity and mortality.

### Prognosis

The great majority of thyroid nodules are benign. Benign thyroid nodules may involute but usually persist or grow slowly. About 90% of thyroid nodules will increase their volume by ≥15% over 5 years; cystic nodules are less likely to grow. Cytologically benign nodules that grow are unlikely to be malignant; in one series, only 1 of 78 rebiopsied nodules was found to be malignant. The prognosis for patients with thyroid nodules that prove to be malignant is determined by the histologic type and other factors (see below). Multinodular goiters tend to persist or grow slowly, even in iodine-deficient areas where iodine repletion usually does not shrink established goiters. Patients with very small, incidentally discovered, nonpalpable thyroid nodules do require follow-up with thyroid ultrasound every 1–2 years but are at low risk for malignancy. Nodules that are malignant have a minor effect on morbidity and mortality.

### General Considerations

The incidence of papillary and follicular (differentiated) thyroid carcinomas increases with age. The overall female: male ratio is 3:1. The yearly incidence of thyroid cancer has been increasing in the United States, with the number of cases diagnosed annually reaching 37,200, probably as a result of the wider use of CT, MRI, PET, and ultrasound that incidentally find small thyroid malignancies. Thyroid cancer mortality has been stable, accounting for about 1500 deaths in the United States annually. Thyroid microcarcinoma (≤10 mm diameter) is found with the surprising frequency of 35%. Clearly, most thyroid cancers remain microscopic and indolent. However, larger thyroid cancers (palpable or ≥1 cm in diameter) are more malignant and require treatment.

**Papillary thyroid carcinoma** is the most common thyroid malignancy (Table 26–7).

Pure papillary and mixed papillary-follicular carcinoma represent about 80% of all thyroid cancers. It usually presents as a single thyroid nodule, but it can arise out of a multinodular goiter. Papillary thyroid carcinoma is commonly multifocal within the gland, with other foci usually arising de novo rather than representing intraglandular metastases. About 10% of cases present with palpable cervical lymph node metastases from a small thyroid cancer. Papillary thyroid carcinomas tend to grow slowly and often remain confined to the thyroid and regional lymph nodes for years. However, they may become more aggressive, especially in patients over age 45 years, and most particularly in the elderly. The cancer may invade the trachea and local muscles and may spread to the lungs.

Papillary thyroid carcinoma is caused by genetic mutations or translocations. Activating mutations of the ras oncogene can cause benign thyroid adenomas or nodular goiter. Additional activating mutations in BRAF or TRK genes can lead to papillary carcinoma. About 45% of papillary thyroid carcinomas are caused by over expression of the ret oncogene by the translocation of certain gene promoters to it, producing retPTC-1, retPTC-2, or retPTC-3. Radiation treatments to the head and neck region tend to cause retPTC-1. Nuclear fallout exposure tends to cause retPTC-3, resulting in more aggressive papillary thyroid carcinomas. Additional loss of the p53 tumor suppressor gene can cause progression of papillary thyroid carcinoma to anaplastic thyroid carcinoma.

Exposure to head and neck radiation therapy poses a particular threat to children who then have an increased lifetime risk of developing thyroid pathology, including papillary thyroid carcinoma; thyroid malignancy may emerge between 10 and 40 years after exposure, with a peak occurrence 20–25 years later. After an explosion at the Chernobyl Nuclear Plant in the Ukraine in 1986, the risk of developing papillary thyroid carcinoma was highest among children who were under age 5 at the time of exposure to radiation; emergence of more aggressive papillary thyroid carcinoma occurred within 6–7 years after exposure.

Papillary thyroid carcinoma can occur in familial syndromes as an autosomal dominant trait, caused by loss of various tumor suppressor genes. Such syndromes (with associated features) include familial papillary carcinoma.

---

### Essential of Diagnosis

- **Painless swelling in region of thyroid.**
- **Thyroid function tests usually normal.**
- **Past history of irradiation to head and neck region may be present.**
- **Positive thyroid needle aspiration.**
(with papillary renal carcinoma); familial nonmedullary thyroid carcinoma; familial polyposis (with large intestine polyps and gastrointestinal tumors); Gardner syndrome (with small and large intestine polyps, fibromas, lipomas, osteomas); and Turcot syndrome (with large intestine polyps and brain tumors). Older patients with multinodular goiter may rarely develop a papillary thyroid carcinoma. Papillary carcinoma can sometimes undergo a late anaplastic transformation into an aggressive carcinoma.

Generally speaking, papillary carcinoma is the least aggressive thyroid malignancy. However, the tumor spreads via lymphatics within the thyroid, appearing to be multifocal in 60% of patients and involving both lobes in 30% of patients. About 80% of patients have microscopic metastases to cervical lymph nodes. Unlike other forms of cancer, patients with papillary thyroid carcinoma who have palpable lymph node metastases do not have a particularly increased mortality rate; however, their risk of local recurrence is increased.

Occult metastases to the lung occur in 10–15% of papillary thyroid cancer. About 70% of small lung metastases resolve following 131I therapy; however, larger pulmonary metastases have only a 10% remission rate.

Microscopic “micropapillary” carcinoma (≤ 1 mm and invisible even on thyroid ultrasound) is a variant of normal, being found in 24% of thyroidectomies performed for benign thyroid disease when 2-mm sections were carefully examined. It thus appears that the overwhelming majority of these microscopic foci never become clinically significant. The surgical pathology report of such a tiny papillary carcinoma that is otherwise benign does not justify aggressive follow-up or treatment because a cancer diagnosis is unwarranted and harmful. All that may be required is yearly follow-up with palpation of the neck and mild TSH suppression by thyroxine.

**Follicular thyroid carcinoma** and its variants (eg, Hürthle cell carcinoma) account for about 14% of thyroid malignancies; follicular thyroid carcinoma is generally more aggressive than papillary carcinoma. Rarely, some follicular carcinomas secrete enough T3 to cause thyrotoxicosis if the tumor load becomes significant. Metastases commonly are found in neck nodes, bones, and lungs. Most follicular thyroid carcinomas avidly absorb iodine, making possible diagnostic scanning and treatment with 131I after total thyroidectomy. The follicular histopathologic features that are associated with a high risk of metastasis and recurrence are poorly differentiated and Hürthle cell (oncocytic) variants. The latter variants do not take up RAI.

Follicular carcinoma results from certain gene mutations or translocations. Aberrant DNA methylation, activation of the ras oncogene, and mutations of the MEN1 gene can result in benign follicular adenomas. Loss of function of PPARγ or the 3P tumor suppressor gene can lead to follicular carcinoma, and additional loss of the p53 tumor suppressor gene can produce anaplastic carcinoma.

Follicular thyroid carcinoma and adenomas develop in patients with Cowden disease, a rare autosomal dominant familial syndrome caused by loss of a tumor suppressor gene; such patients tend to have macrocephaly, multiple hamartomas, early-onset breast cancer, intestinal polyps, facial papules, and other skin and mucosal lesions.

**Medullary thyroid carcinoma** represents about 3% of thyroid cancers. About one-third of cases are sporadic, one-third are familial, and one-third are associated with MEN type 2. Medullary thyroid carcinoma is often caused by an activating mutation of the ret oncogene on chromosome 10. Mutation analysis of the ret oncogene exons 10, 11, 13, and 14 detects 95% of the mutations causing MEN 2A and 90% of the mutations causing familial medullary thyroid carcinoma. Patients with MEN 2B have activating mutations in exon 16 of the ret oncogene. These germline mutations can be detected by DNA analysis of peripheral WBCs. Therefore, discovery of a medullary thyroid carcinoma makes genetic analysis mandatory. If a gene defect is discovered, related family members must have genetic screening for that specific gene defect. When a family member with MEN 2A or familial medullary thyroid carcinoma does not have an identifiable ret oncogene mutation, gene carriers may still be identified using family linkage analysis. Even when no gene defect is detectable, family members should have thyroid surveillance every 6 months. Somatic mutations of the ret oncogene can be identified in

</table>
the tumors of 30% of patients with sporadic (nonfamilial) medullary thyroid carcinoma. (See Multiple Endocrine Neoplasia.)

Medullary thyroid carcinoma arises from parafollicular thyroid cells that can secrete calcitonin, prostaglandins, serotonin, ACTH, corticotropin-releasing hormone (CRH), and other peptides. These peptides can cause symptoms and can be used as tumor markers. Early local metastases are usually present, usually to adjacent muscle and trachea as well as to local and mediastinal lymph nodes. Eventually, late metastases may appear in the bones, lungs, adrenal glands, or liver. Medullary thyroid carcinoma does not concentrate iodine.

**Anaplastic thyroid carcinoma** represents about 2% of thyroid cancers. It usually presents in an older patient as a rapidly enlarging mass in a multinodular goiter. It is the most aggressive thyroid carcinoma and metastasizes early to surrounding nodes and distant sites. Local pressure symptoms include dysphagia or vocal cord paralysis. This tumor does not concentrate iodine.

Anaplastic thyroid carcinoma is caused by certain gene mutations, including inactivating mutations of the p53 tumor suppressor gene, as described above for papillary and follicular thyroid carcinomas.

Other thyroid malignancies together represent about 3% of thyroid cancers. **Lymphoma** of the thyroid is more common in older women. Thyroid lymphomas are most commonly B cell lymphomas (50%) or mucosa-associated lymphoid tissue (MALT; 23%); other types include follicular, small lymphocytic, and Burkitt lymphoma and Hodgkin disease. Thyroidectomy is rarely required. **Other cancers** may sometimes metastasize to the thyroid, particularly bronchogenic, breast, and renal carcinomas and malignant melanoma.

### Clinical Findings

#### A. Symptoms and Signs

Thyroid carcinoma usually presents as a palpable, firm, nontender nodule in the thyroid. Most thyroid carcinomas are asymptomatic, but large thyroid cancers can cause neck discomfort, dysphagia, or hoarseness (due to pressure on the recurrent laryngeal nerve). About 3% of thyroid malignancies present with a metastasis, usually to distant sites such as bone or lung. Palpable lymph node involvement is present in 15% of adults and 60% of youths. Metastatic functioning differentiated thyroid carcinoma can sometimes secrete enough thyroid hormone to produce thyrotoxicosis. **Anaplastic thyroid carcinoma** is more apt to be advanced at the time of diagnosis, presenting with dysphagia, hoarseness, dyspnea, and metastases to the lungs. Occasionally, such carcinomas may be discovered while they are still relatively small and localized.

**Medullary thyroid carcinoma** frequently causes flushing and persistent diarrhea (30%), which may be the initial clinical feature. Patients with metastases often experience fatigue as well as other symptoms. Cushing syndrome develops in about 5% of patients from secretion of ACTH or CRH. Signs of pressure or invasion of surrounding tissues are present in anaplastic or large tumors; recurrent laryngeal nerve palsy can occur.

**Lymphoma** usually presents as a rapidly enlarging, painful mass arising out of a multinodular or diffuse goiter affected by autoimmune thyroiditis, with which it may be confused microscopically. About 20% of cases have concomitant hypothyroidism.

#### B. Laboratory Findings

(FNA biopsy is discussed above in the section on Thyroid Nodules.) Thyroid function tests are generally normal unless there is concomitant thyroiditis. Follicular carcinoma may secrete enough T₄ to suppress TSH and cause clinical hyperthyroidism.

Serum thyroglobulin is high in most metastatic papillary and follicular tumors, making this a useful marker for recurrent or metastatic disease. Caution must be exercised for the following reasons: (1) Circulating antithyroglobulin antibodies can cause erroneous thyroglobulin determinations. (2) Thyroglobulin levels may be misleadingly elevated in thyroiditis, which often coexists with carcinoma. (3) Certain thyroglobulin assays falsely report the continued presence of thyroglobulin after total thyroidectomy and tumor resection, causing undue concern about possible metastases. Therefore, unexpected thyroglobulin levels should prompt a repeat assay in another reference laboratory.

Serum calcitonin levels are usually elevated in medullary thyroid carcinoma, making this a marker for metastatic disease. However, serum calcitonin may be elevated in many other conditions, such as thyroiditis; pregnancy; azotemia; hypercalcemia; and other malignancies, including pheochromocytomas, carcinoid tumors, and carcinomas of the lung, pancreas, breast, and colon.

In patients with **medullary thyroid carcinoma**, serum calcitonin and carcinoembryonic antigen (CEA) determinations should be obtained before surgery, then regularly in postoperative follow-up: every 4 months for 5 years, then every 6 months for life. In patients with extensive metastases, serum calcitonin should be measured in the laboratory with serial dilutions. Calcitonin levels remain elevated in patients with persistent tumor but also in some patients with apparent cure or indolent disease. Therefore, rising levels of calcitonin (or CEA) are the best indication for recurrence. Serum calcitonin levels > 250 pg/mL are also an indication for recurrent or metastatic medullary thyroid carcinoma. Serum CEA levels are usually elevated with medullary carcinoma, making this a useful second marker; however, it is not specific for this carcinoma.

#### C. Imaging

1. **Ultrasound of the neck**—Ultrasound of the neck should be performed routinely on all patients with thyroid cancer for the initial diagnosis and for follow-up. Ultrasound is useful in determining the size and location of the malignancy as well as the location of any neck metastases.

2. **Radioactive iodine scanning**—RAI (¹³¹I or ¹²³I) thyroid and whole-body scanning is used after thyroidectomy for surveillance as described below, supplanting its previous
use to determine whether a nodule was “cold” as a sign of malignancy.

3. CT and MRI scanning—CT scanning may demonstrate metastases and is particularly useful for localizing and monitoring lung metastases. However, CT scanning is less sensitive than ultrasound for detecting metastases within the neck. Iodinated contrast should never be given prior to RAI scanning or RAI therapy, since the large amounts of iodine in contrast media competitively inhibit the uptake of RAI by the thyroid, greatly reducing the effectiveness of subsequent RAI scanning and therapy. Medullary carcinoma in the thyroid, nodes, and liver may calcify, but lung metastases rarely do so. MRI is particularly useful for imaging bone metastases.

4. PET scanning—PET scanning is particularly useful for detecting thyroid cancer metastases that do not have sufficient iodine uptake to be visible on RAI scans. Metastases are best detected using 18FDG-PET whole-body scanning. The sensitivity of 18FDG-PET scanning for differentiated thyroid cancer is enhanced if the patient is hypothyroid or receiving thyrotropin, which increases the metabolic activity of differentiated thyroid cancer. Disadvantages of PET scanning include its lack of specificity for thyroid cancer as well as its expense and lack of availability in some locations. 18FDG-PET scanning has prognostic implications, since differentiated thyroid cancer metastases with low standard uptake value (SUV) scores are associated with a better prognosis.

Differential Diagnosis

Neuroendocrine carcinomas may metastasize to the thyroid and be confused with medullary thyroid carcinoma. False-positive 131I scans are common with normal residual thyroid tissue and have been reported with Zenker diverticulum, struma ovarii, pleuropericardial cyst, gastric pull-up, and 131I-contaminated bodily secretions. False-negative 131I scans are common in early metastatic differentiated thyroid carcinoma but occur also in more advanced disease, including 14% of bone metastases.

Complications

The complications vary with the type of carcinoma. Differentiated thyroid carcinomas may have local or distant metastases. One-third of medullary carcinomas may secrete serotonin and prostaglandins, producing flushing and diarrhea, and may be complicated by the coexistence of pheochromocytoma or hyperparathyroidism. The risks of radical neck surgery include permanent hypoparathyroidism and vocal cord palsy due to recurrent laryngeal nerve damage; permanent hypothyroidism is expected after thyroidectomy and should always be treated adequately.

Treatment of Differentiated Thyroid Carcinoma

A. Surgical Treatment

Surgical removal is the treatment of choice for thyroid carcinomas. Neck ultrasound is obtained preoperatively, since suspicious cervical lymphadenopathy is detected in about 25%. Intraoperative thyroid ultrasound by the surgeon also helps assess the extent of the tumor and lymph node involvement, altering surgical treatment in many cases. For differentiated papillary and follicular carcinoma > 1 cm diameter, total thyroidectomy is performed with limited removal of cervical lymph nodes. For medullary thyroid carcinoma, repeated neck dissections are often required.

For indeterminate nodules, surgery consists of a thyroid lobectomy for an indeterminate “follicular lesion” that is ≤ 4 cm diameter. If malignancy is diagnosed on pathology, a completion thyroidectomy is performed. For indeterminate follicular lesions > 4 cm diameter that are at higher risk for being malignant, a bilateral thyroidectomy is performed as the initial surgery. Higher risk lesions include those with a FNA biopsy that shows marked atypia or that are suspicious for papillary carcinoma and those that occur in patients with a history of radiation exposure or a family history of thyroid carcinoma.

For biopsies that are diagnostic of malignancy, surgery involves lobectomy alone for papillary thyroid carcinomas < 1 cm diameter in patients under age 45 years who have no history of head and neck irradiation and no evidence of lymph node metastasis on ultrasonography. Other patients should have a total or near total thyroidectomy. The advantage of near-total thyroidectomy for differentiated thyroid carcinoma is that multicentric focci of carcinoma are more apt to be resected. Also, there is less normal thyroid tissue to compete with cancer for 131I administered later for scans or treatment. A central neck lymph node dissection is performed at the time of thyroidectomy for patients with nodal metastases that are clinically evident. A lateral neck dissection is performed for patients with biopsy-proven lateral cervical lymphadenopathy. Neck muscle resections are usually avoided for differentiated thyroid carcinoma. However, patients with the Hurthle cell variant of follicular carcinoma may benefit from a modified radical neck dissection. Metastases to the brain are best treated surgically, since treatment with radiation or RAI is ineffective. Levothyroxine is prescribed in doses of 0.05–0.1 mg orally daily immediately postoperatively (see Thyroxine Suppression and Chemotherapy, below). About 2–4 months after surgery, patients require reevaluation and often require therapy with 131I (see below).

Permanent injury to one recurrent laryngeal nerve occurs in between 1–2% and 7% of patients, depending on the experience of the surgeon. Bilateral nerve palsies are rare. Temporary recurrent laryngeal nerve palsies occur in another 5% but often resolve within 6 months. After total thyroidectomy, temporary hypoparathyroidism occurs in 20% and becomes permanent in about 2%. The incidence of hypoparathyroidism may be reduced if accidentally resected parathyroids are immediately autotransplanted into the neck muscles. Thyroidectomy requires at least an overnight hospital admission, since late bleeding, airway problems, and tetany may occur. Ambulatory thyroidectomy is potentially dangerous and should not be done. Following surgery, staging (Table 26–8) should be done to help determine prognosis and to plan therapy and follow-up.
In pregnant women with thyroid cancer, surgery is usually delayed until after delivery, except for fast-growing tumors that may be resected after 24 weeks gestation; there has been no difference in survival or tumor recurrence rates in women who underwent surgery during or after their pregnancy. Differentiated thyroid carcinoma does not behave more aggressively during pregnancy. But there is a higher risk of complications in pregnant women undergoing thyroid surgery, compared to nonpregnant women.

**B. Thyroxine Suppression and Chemotherapy**

Patients who have had a thyroidectomy for differentiated thyroid cancer must take thyroxine replacement for life. Oral thyroxine should be given in doses that suppress serum TSH below 0.05 mU/L for patients with stage III–IV disease. Although patients receiving thyroxine suppression therapy are advised to have periodic bone densitometry. Nevertheless, patients receiving thyroxine suppression therapy are at risk for a minor for patients who remain clinically euthyroid. Zoledronic acid, an intravenous bisphosphonate, has proven useful for osteolytic metastases from other solid tumors and has been used for patients with thyroid bone metastases, but its effectiveness is unknown.

Thyroid carcinomas are extraordinarily resistant to chemotherapy. Sorafenib and sunitinib are tyrosine kinase inhibitors that have shown some activity against metastatic differentiated thyroid carcinomas that are radioiodine-resistant, with partial responses in 20% and stable disease in 60%.

**C. Radioactive Iodine (131I) Therapy**

Differentiated thyroid cancers variably retain the normal thyroid’s ability to respond to TSH, secrete thyroglobulin, and concentrate iodine. There are two reasons to treat patients with 131I after thyroidectomy: (1) thyroid remnant ablation and (2) treatment of known or suspected thyroid cancer. 131I is usually administered 2–4 months after surgery. Treatment with 131I is repeated 9–12 months later if surveillance RAI scanning shows evidence of metastatic disease. (See Surveillance, below.)

Before starting 131I therapy, patients follow a low iodine diet for at least 2 weeks. The low iodine diet consists of avoiding the following: iodized table salt, sea salt, fish, shellfish, seaweed, commercial bread, dairy products, processed meats, canned or dried fruit, canned fruit juices, highly salted soups and snack foods, black tea, instant coffee, food coloring with Red Dye #3, egg yolks, multivitamins with iodine, or topical iodine. Patients must not be given amiodarone or intravenous radiologic contrast dyes containing iodine.

**1. Thyroid remnant ablation**—A small dose of 30 mCi (1110 MBq) 131I is given for “remnant ablation” of residual normal thyroid tissues after surgery for differentiated thyroid cancer. This small dose of 131I is given to patients with no lymph node involvement who are at low risk for metastases. There are several advantages for giving thyroid remnant ablation: (1) There is usually remnant normal tissue that can produce thyroglobulin (a useful tumor marker); (2) Remnant ablation using 131I may destroy microscopic deposits of cancer; (3) The post-therapy scan may visualize metastatic cancer that would otherwise have been invisible. However, 131I remnant ablation has not been useful for patients with stage I papillary thyroid carcinomas < 1 cm diameter that are unifocal or multifocal. Such very low-risk patients may have close surveillance without receiving remnant ablation.

**2. Treatment of metastases**—RAI therapy improves survival and reduces recurrence rates for patients with stage III-IV cancer and those with stage II cancer having gross extrathyroidal extension. RAI therapy is also given to patients with stage II cancer who have distant metastases, a primary tumor > 4 cm diameter, or primary tumors 1–4 cm diameter with lymph node metastases or other high-risk features. Brain metastases do not usually respond

---

1Patients having a relatively worse prognosis include those with familial differentiated thyroid carcinoma.
to $^{131}$I and are best resected or treated with gamma knife radiosurgery (Table 26–8). A post-therapy whole-body scan is performed 2–10 days after $^{131}$I therapy.

Staging with RAI scanning or $^{18}$FDG-PET/CT scanning assists dosing decisions for $^{131}$I therapy. Radioiodine doses of 50–100 mCi are given to patients with large primary tumors or tumors at the surgical margin. Patients with local lymph node involvement typically receive 100 mCi of $^{131}$I; patients with more extensive neck node involvement, regional or distant metastases receive $^{131}$I at a dose of 125–200 mCi (4625–7400 MBq). Unfortunately, about 35% of patients with differentiated thyroid carcinoma have poor uptake of $^{131}$I into metastases. Patients with asymptomatic, stable, radioiodine-resistant metastases may be carefully monitored for tumor progression.

Some patients have elevated serum thyroglobulin levels but a negative whole-body radioiodine scan and a negative neck ultrasound. In such patients, an $^{18}$F-FDG PET/CT scan is obtained. If all scans are negative, empiric therapy with $^{131}$I is not useful.

Doses of $^{131}$I over 100 mCi (3800 MBq) can cause gastritis, temporary oligospermia, sialadenitis, and xerostomia. RAI therapy can cause neurologic decapsulation in patients with brain metastases; it is advisable to treat such patients with prednisone 30–40 mg orally daily for several days before and after $^{131}$I therapy. Cumulative doses of $^{131}$I over 500 mCi can cause infertility, pancytopenia (4%), and leukemia (0.3%). Pulmonary fibrosis can occur in patients with diffuse lung metastases after receiving cumulative $^{131}$I activities of > 600 mCi (22 GBq). The kidneys excrete RAI, so patients receiving dialysis for kidney disease require a dosage reduction to only 20% of the usual dose of $^{131}$I.

### 3. rTSH-stimulated $^{131}$I therapy, thyroglobulin, and scan

Recombinant human thyroid stimulating hormone (rTSH, Thyrogen) is given to increase the sensitivity of serum thyroglobulin for residual cancer and to increase the uptake of $^{131}$I into residual thyroid tissue (thyroid remnant “ablation”) or cancer. Thyrogen must be kept refrigerated and is administered according to the following protocol: Thyroxine replacement is held for 2 days before rTSH and for 3 days afterward. rTSH 0.9 mg is administered intragastrically (not intravenously) daily for 2 consecutive days. On the third day, blood is drawn: serum TSH is assayed to confirm that it is > 30 mcU/mL; serum hCG is measured in reproductive-age women to screen for pregnancy; and serum thyroglobulin is measured as a tumor marker. RAI is then administered at the prescribed dose (see above).

Thyrogen should not be administered to patients with an intact thyroid gland because it can cause severe thyroid swelling and hyperthyroidism. Hyperthyroidism can also occur in patients with significant metastases or residual normal thyroid. Other side effects include nausea (11%) and headache (7%). Thyrotropin has caused neurologic deterioration in 7% of patients with central nervous system metastases.

### 4. Thyroxine-withdrawal stimulated $^{131}$I therapy, thyroglobulin, and scan

Thyroxine withdrawal is sometimes used because of its lower cost, despite the discomforts of becoming hypothyroid. Thyroxine is withdrawn for 14 days and the patient is allowed to become hypothyroid; high levels of endogenous TSH stimulate the uptake of RAI and production of thyroglobulin by thyroid cancer or residual thyroid. Just prior to $^{131}$I therapy, the following blood tests are obtained: serum TSH to confirm it is > 30 mcU/mL, serum hCG in reproductive-age women to screen for pregnancy, serum thyroglobulin as a tumor marker. Three days after $^{131}$I therapy, thyroxine therapy may be resumed at full replacement dose.

### 5. Side effects and contraindications

National Cancer Institute surveillance data for thousands of patients with thyroid cancer indicate that patients with differentiated thyroid cancer, treated with only surgery, have a 5% increased risk of developing a second non-thyroid malignancy (especially breast cancer). Patients with thyroid cancer who received $^{131}$I therapy have a 20% increased risk of developing a second non-thyroid malignancy (especially leukemia and lymphoma). The greatest risk of second cancers appeared within 5 years of $^{131}$I therapy and was most significant for younger patients.

Pregnant women may not receive RAI therapy. Women are advised to avoid pregnancy for at least 4 months following $^{131}$I therapy. Men have been found to have abnormal spermatogenesis for up to 6 months following $^{131}$I therapy and are advised to use contraceptive methods during that time.

#### Treatment of Other Thyroid Malignancies

Patients with anaplastic thyroid carcinoma are treated with local resection and radiation. Lovastatin has been demonstrated to cause differentiation and apoptosis of anaplastic thyroid carcinoma cells in vitro; however, clinical studies have not been performed. Anaplastic thyroid carcinoma does not respond to $^{131}$I therapy and is resistant to chemotherapy.

Patients with thyroid MALT lymphomas have a low risk of recurrence after simple thyroidectomy. Patients with other thyroid lymphomas are best treated with external radiation therapy; chemotherapy is added for extensive lymphoma. Patients with systemic lymphomas involving the thyroid are usually treated with chemotherapy. Patients with a ret protooncogene mutation should have a prophylactic total thyroidecetomy, ideally by age 6 years (MEN 2A) or at age 6 months (MEN 2B). Medullary thyroid carcinoma is best treated with surgery for the primary tumor and metastases. It does not respond to $^{131}$I therapy and is generally resistant to chemotheraphy. In one study, vandetanib (100 mg orally once daily) produced a partial remission in 16% and stable disease in 53% of patients with locally advanced or metastatic medullary thyroid carcinoma.

#### A. External Radiation Therapy

External radiation may be delivered to bone metastases, especially those without radioiodine uptake. Local neck radiation therapy may also be given to patients with anaplastic thyroid carcinoma. Brain metastases can be treated with gamma knife radiosurgery.
Surveillance

Patients with differentiated thyroid carcinoma must be observed long-term for recurrent or metastatic disease. Patients with differentiated thyroid carcinoma have traditionally required at least two annual consecutively negative stimulated serum thyroglobulin determinations < 1 ng/mL and normal RAI scans (if done) and neck ultrasound before they are considered to be in remission. The first surveillance occurs with stimulated postoperative serum thyroglobulin, ¹³¹I therapy, and post-therapy scanning about 2–4 months after surgery. (See Treatment, above.) At 9–12 months postoperatively, patients usually receive another stimulated serum thyroglobulin and radioiodine scan. Patients with persistent RAI uptake restricted to the thyroid bed need not have repeated ¹³¹I therapies if the neck ultrasound appears normal and stimulated serum thyroglobulin is < 2 ng/mL. Further radioiodine or other scans may be required for patients with more aggressive differentiated thyroid cancer, prior metastases, rising serum thyroglobulin levels, or other evidence of metastases.

1. Serum TSH suppression—Patients with differentiated thyroid cancer are treated with thyroxine doses that are sufficient to suppress the serum TSH below the normal range. For intermediate- or high-risk patients, the serum TSH should be suppressed below 0.1 mU/L, while the target TSH for low-risk patients is 0.1–0.5 mU/mL. Patients who are considered cured should nevertheless be treated with sufficient thyroxine to keep the serum TSH < 2 mU/L. Follow-up must include physical examinations and laboratory testing to ensure that patients remain clinically euthyroid with serum TSH levels in the target range. To achieve suppression of serum TSH, the required dose of thyroxine may be such that serum FT₄ levels may be slightly elevated; in that case, measurement of serum T₃ or free T₃ can be useful to ensure the patient is not frankly hyperthyroid. Thyrotoxicosis can be caused by overreplacement with thyroxine or by the growth of functioning metastases.

2. Serum thyroglobulin—Thyroglobulin is produced by normal thyroid tissue and by most differentiated thyroid carcinomas. It is only after a total or near-total thyroidectomy and ¹³¹I remnant ablation that thyroglobulin becomes a useful tumor marker for patients with differentiated papillary or follicular thyroid cancer, particularly for patients who do not have serum antithyroglobulin antibodies.

Detectable thyroglobulin levels do not necessarily indicate the presence of residual or metastatic thyroid cancer. Conversely, baseline serum thyroglobulin levels are insensitive markers for disease recurrence. However, baseline or stimulated serum thyroglobulin levels ≥ 2 ng/mL indicate the need for a repeat neck ultrasound and further scanning with RAI or ¹⁸FDG-PET. If serum thyroglobulin levels remain ≥ 2 ng/mL in the presence of normal scanning, it is prudent to repeat the serum thyroglobulin in a national reference laboratory. In one series of patients with differentiated thyroid cancer following thyroidectomy, there was a 21% incidence of metastases in patients with serum thyroglobulin < 1 ng/mL (while receiving thyroxine for TSH suppression). Therefore, baseline serum thyroglobulin levels are inadequately sensitive and stimulated serum thyroglobulin measurements should be used and always with neck ultrasound. The usefulness of routinely doing a radioiodine scan (see below) in low-risk patients is controversial but continues to be done in many centers during stimulation following either rhTSH or thyroid hormone withdrawal, according to described protocols.

3. Neck ultrasound—Neck ultrasound should be used in all patients with thyroid carcinoma to supplement neck palpation; it should be performed preoperatively, 3 months postoperatively, and regularly thereafter. Ultrasound is more sensitive for lymph node metastases than either CT or MRI scanning. Small inflammatory nodes may be detected postoperatively and do not necessarily indicate metastatic disease, but follow-up is necessary. Ultrasound-guided FNA biopsy should be performed on suspicious lesions.

4. Radioactive iodine (RAI: ¹³¹I or ¹²³I) neck and whole-body scanning—Despite its limitations, RAI scanning has traditionally been used to detect metastatic differentiated thyroid cancer and to determine whether the cancer is amenable to treatment with ¹³¹I. RAI scanning is particularly useful for high-risk patients and those with persistent antithyroglobulin antibodies that make serum thyroglobulin determinations unreliable.

The ¹³¹I isotope may be used in scanning doses, given < 2 weeks before scheduled ¹³¹I treatment to avoid “stunning” metastases such that they take up less of the RAI therapy dose. The radioisotope ¹²³I may also be used and does not stun tumors; it allows single-photon emission computed tomography (SPECT) to better localize metastases. Initial RAI scanning is typically performed about 2–4 months following surgery for differentiated thyroid carcinoma. Whole-body scanning should be performed for at least 30 minutes for at least 140,000 counts and spot views of the neck should be obtained for at least 35,000 counts.

About 63% of metastases are detectable by RAI scanning, but only after optimal preparation: Patients should ideally have a total or near-total thyroidectomy, since any residual normal thyroid competes for RAI with metastases, which are less avid for iodine. It is reasonable to perform a rhTSH-stimulated scan and thyroglobulin level 2–3 months after the initial neck surgery; if the scan is negative and the serum thyroglobulin is < 2 ng/mL, low-risk patients may not require further scanning but should continue to be monitored with neck ultrasound and serum thyroglobulin levels every 6–12 months. For higher-risk patients, the rhTSH-stimulated thyroglobulin and RAI scan may be repeated about 1 year after surgery and then again if warranted. Serum thyroglobulin and radioiodine scanning are stimulated by either rhTSH or thyroid hormone withdrawal according to the protocols described above for ¹³¹I treatment.

The combination of rhTSH-stimulated scanning and thyroglobulin levels detects a thyroid remnant or cancer with a sensitivity of 84%. However, the presence of antithyroglobulin antibodies renders the serum thyroglobulin determination uninterpretable. In about 21% of low-risk patients, rhTSH stimulates serum thyroglobulin to above 2 ng/mL; such patients have a 23% risk of local neck
metastases and a 13% risk of distant metastases. The rhTSH-stimulated radioiodine neck and whole-body scan detects only about half of these metastases because they are small or not avid for iodine. Some patients have persistent radioiodine uptake in the neck on diagnostic scanning but have no visible tumor on neck ultrasound; such patients do not require additional radioiodine therapy, especially if the serum thyroglobulin level is very low.

5. Positron emission tomography scanning—$^{18}$FDG-PET scanning is particularly useful for detecting thyroid cancer metastases in patients with a detectable serum thyroglobulin (especially serum thyroglobulin levels >10 ng/mL and rising) who have a normal whole-body RAI scan and an unrevealing neck ultrasound. The patient should be fasting at least 6 hours prior to $^{18}$FDG-PET scanning; water is allowed, but no sweetened beverages. Diabetic patients with blood sugars < 200 mg/dL may be scanned. $^{18}$FDG-PET scanning can be combined with a CT scan; the resultant $^{18}$FDG-PET/CT fusion scan is 60% sensitive for detecting metastases that are not visible by other methods. This scan is less sensitive for small brain metastases. $^{18}$FDG-PET scanning detects the metabolic activity of tumor tissue; for differentiated thyroid carcinoma, this scan is more sensitive when the patient's thyroid cancer is stimulated with rhTSH (Thyrogen) as described above. One problem with $^{18}$FDG-PET scanning is its lack of specificity. False-positives can occur with benign hepatic tumors, sarcoidosis, radiation therapy, suture granulomas, reactive lymph nodes, or inflammation at surgical sites that can persist for months. False-positive uptake can also occur in muscles and brown fat.

$^{18}$FDG-PET scanning predicts survival better than standard staging; the number, location, and SUV$_{max}$ of metastases are all significant prognostic factors. (See Prognosis.) $^{18}$FDG-PET scanning is particularly sensitive for detecting medullary thyroid carcinoma metastases, and prescan thyrotropin does not improve the PET scan sensitivity for medullary thyroid carcinoma.

6. Other scanning—Thallium-201 ($^{201}$TI) scans may be useful for detecting metastatic differentiated thyroid carcinoma when the $^{131}$I scan is normal but serum thyroglobulin is elevated. MRI scanning is particularly useful for imaging metastases in the brain, mediastinum, or bones. CT scanning is useful for imaging and monitoring pulmonary metastases.

### Prognosis

Papillary thyroid cancer staging and survival data are shown on Table 26–8. $^{18}$FDG-PET scanning independently predicts survival, with patients having few PET-avid metastases and low SUV$_{max}$ (highest image-pixel standardized uptake value) having a better prognosis. There is generally a good prognosis, particularly for adults under age 45 years, despite the fact that up to 40% of these patients are found to harbor lymph node metastases when extensive lymph node dissections are performed. The following characteristics imply a worse prognosis: age over 45 years, male sex, bone or brain metastases, macronodular (> 1 cm) pulmonary metastases, and lack of $^{131}$I uptake into metastases. Younger patients with pulmonary metastases tend to respond better to $^{131}$I therapy than do older adults. Certain papillary histologic types are associated with a higher risk of recurrence and reduced survival: tall cell, columnar cell, and diffuse sclerotic types. Brain metastases are detected in 1%; they reduce median survival to 12 months, but the patient’s prognosis is improved by surgical resection.

Patients with a follicular variant of papillary carcinoma have a prognosis somewhere between that of papillary and follicular thyroid carcinoma.

Patients with follicular carcinoma have a cancer mortality rate that is 3.4 times higher than patients with papillary carcinoma. The Hurthle cell variant of follicular carcinoma is even more aggressive. Both follicular carcinoma and its Hurthle cell variant tend to present at a more advanced stage than papillary carcinoma. However, at a given stage, the different types of differentiated thyroid carcinoma have a similar prognosis. Patients with primary tumors > 1 cm in diameter who undergo limited thyroid surgery (subtotal thyroidectomy or lobectomy) have a 2.2-fold increased mortality over those having total or near-total thyroidectomies. Patients who have not received $^{131}$I ablation have mortality rates that are increased twofold by 10 years and threefold by 25 years (over those who have received ablation). The risk of cancer recurrence is twofold higher in men than in women and 1.7-fold higher in multifocal than in unifocal tumors.

Patients with a normal $^{18}$FDG-PET scan have a 98% 5-year survival, while those having >10 metastases have a 20% 5-year survival. Those with a SUV$_{max}$ of 0.1-4.6 have a 5-year survival of 85%, while those with a SUV$_{max}$ > 13.3 have a 5-year survival of 20%. Patients with only local metastases have a 5-year survival of 95%, while those with regional (supraclavicular, mediastinal) metastases have a 5-year survival of 70%, and those with distant metastases have a 5-year survival of 35%.

Medullary thyroid carcinoma is more aggressive than differentiated thyroid cancer but is typically fairly indolent. The overall 10-year survival rate is 90% when the tumor is confined to the thyroid, 70% for those with metastases to cervical lymph nodes, and 20% for those with distant metastases. Patients with sporadic disease usually have lymph node involvement noted at the time of diagnosis, whereas distal metastases may not be noted for years. For patients with medullary thyroid carcinoma who have metastases to lymph nodes, modified radical neck dissection is recommended. Familial cases or those associated with MEN 2A tend to be less aggressive; the 10-year survival rate is higher, in part due to earlier detection. Medullary thyroid carcinoma that is seen in MEN 2B is more aggressive, arises earlier in life, and carries a worse overall prognosis, especially when associated with a germline M918T mutation. The elderly tend to have more aggressive medullary thyroid carcinomas. Women with medullary thyroid carcinoma who are under age 40 years have a better prognosis. A better prognosis is also obtained in patients undergoing total thyroidectomy and neck dissection; radiation therapy reduces recurrence in patients with metastases to neck nodes. The mortality rate is increased 4.5-fold when primary or metastatic tumor tissue stains heavily for myelomonocytic antigen M-1. Conversely,
tumors with heavy immunoperoxidase staining for calcitonin are associated with prolonged survival even in the presence of significant metastases.

**Anaplastic thyroid carcinoma** carries a 1-year survival rate of about 10% and a 5-year survival rate of about 5%. Patients with fully localized tumors on MRI have a better prognosis.

**Localized lymphoma** carries a 5-year survival of nearly 100%. Those with disease outside the thyroid have a 63% 5-year survival. However, the prognosis is better for those with the MALT type. Patients presenting with stridor, pain, laryngeal nerve palsy, or mediastinal extension tend to fare worse.

Jasim S et al. Multiple endocrine neoplasia type 2B with RET proto-oncogene A883F mutation displays a more indolent form of medullary thyroid carcinoma compared with a RET M918T mutation. Thyroid. 2011 Feb;21(2):189–92. [PMID: 21186952]

Kim WG et al. Empiric high-dose 131-iodine therapy lacks efficacy for treated papillary thyroid cancer patients with detectable serum thyroglobulin, but negative cervical sonography and 123I-fluorodeoxyglucose positron emission tomography scan. J Clin Endocrinol Metab. 2010 Mar;95(3):1169–73. [PMID: 20808852]

### General Considerations

About 1 billion people are iodine deficient, having no access to iodized salt and living in areas with iodine-depleted soil. Severe iodine deficiency increases the risk of miscarriage and stillbirth. About 0.5% of live births in iodine-deficient areas have full-blown cretinism. Moderate iodine deficiency during gestation and infancy cause other manifestations of congenital hypothyroidism, such as deafness and short stature and permanently lowers a child’s IQ by 10–15 points.

Populations in areas of iodine deficiency have a high incidence of goiter. One such area is Pescopagano, Italy, where 60% of adults have goiters. Hyperthyroidism (present or past) occurred in 2.9%; hypothyroidism was overt in 0.2% and subclinical in 3.8%.

Although iodine deficiency is the most common cause of endemic goiter, certain foods (eg, sorghum, millet, maize, cassava), mineral deficiencies (selenium, iron), and water pollutants can themselves cause goiter or aggravate a goiter proclivity caused by iodine deficiency. In iodine-deficient patients, smoking can induce goiter growth. Pregnancy aggravates iodine deficiency and is associated with an increase in size of thyroid nodules and the emergence of new nodules. Some individuals are particularly susceptible to goiter owing to congenital partial defects in thyroid enzyme activity.

### Clinical Findings

#### A. Symptoms and Signs

Endemic goiters may become multinodular and very large. Growth often occurs during pregnancy and may cause compressive symptoms.

**Substernal goiters** are usually asymptomatic but can cause tracheal compression, respiratory distress and failure, dysphagia, superior vena cava syndrome, gastrointestinal bleeding from esophageal varices, palies of the phrenic or recurrent laryngeal nerves, or Horner syndrome. Cerebral ischemia and stroke can result from arterial compression or thyrocervical steal syndrome. Substernal goiters rarely cause pleural or pericardial effusions. The incidence of significant malignancy is < 1%.

Some patients with endemic goiter may become hypothyroid. Others may become thyrotoxic as the goiter grows and becomes more autonomous, especially if iodine is added to the diet.

#### B. Laboratory Findings

The serum T4 and TSH are generally normal. TSH falls in the presence of hyperthyroidism if a multinodular goiter has become autonomous in the presence of sufficient amounts of iodine for thyroid hormone synthesis. TSH rises with hypothyroidism. Thyroid RAI uptake is usually elevated, but it may be normal if iodine intake has improved. Serum levels of antithyroid antibodies are usually either undetectable or in low titers. Serum thyroglobulin is often elevated.

### Differential Diagnosis

Endemic goiter must be distinguished from all other forms of nodular goiter that may coexist in an endemic region (see above).
Prevention

Adding iodine to commercial salt prevents iodine deficiency. In the United States, potassium iodide is used. Some tropical countries use potassium iodate, since it is more stable than potassium iodide in hot and humid climates. Iodized salt contains iodine at about 20 mg per kg salt. The minimum dietary requirement for iodine is about 50 mcg daily, with optimal iodine intake being 150–300 mcg daily. Iodine sufficiency is assessed by measurement of urinary iodide excretion, the target being more than 10 mcg/dL. Initiating iodine supplementation in an iodine-deficient area greatly reduces the emergence of new goiters but causes an increased frequency of hyperthyroidism during the first year.

Treatment

The addition of potassium iodide to table salt greatly reduces the prevalence of endemic goiter and cretinism but is less effective in shrinking established goiter. Concurrent deficiencies in both vitamin A and iodine increase the risk of endemic goiter and concurrent repletion of both iodide and vitamin A reduces goiter in endemic goiter regions.

Adults with large multinodular goiter may require thyroidectomy for cosmesis, compressive symptoms, or thyrotoxicosis. Following partial thyroidectomy in iodine-deficient geographic areas, there is a high goiter recurrence rate, so near-total thyroidectomy is preferred when surgery is indicated. Certain patients may be treated with $^{131}$I for large compressive goiters.

Complications

Dietary iodine supplementation increases the risk of autoimmune thyroid dysfunction, which may cause hypothyroidism or hyperthyroidism. Excessive iodine supplementation increases the risk of goiter. Suppression of TSH by administering thyroxine carries the risk of inducing hyperthyroidism, particularly in patients with autonomous multinodular goiters; therefore, thyroxine suppression should not be started in patients with a low TSH level. Rarely, Graves disease can develop 3–10 months after $^{131}$I treatment in patients with large multinodular goiters.

General Considerations

Acquired hypoparathyroidism is most commonly seen following thyroidectomy, when it is usually transient but may be permanent. It may also occur after multiple parathyroidectomies. Hypoparathyroidism may occur transiently after surgical removal of a parathyroid adenoma for primary hyperparathyroidism due to suppression of the remaining normal parathyroids and accelerated remineralization of the skeleton (hungry bone syndrome). Neck irradiation may rarely cause hypoparathyroidism.

Autoimmune hypoparathyroidism may be isolated or combined with other endocrine deficiencies in polyglandular autoimmunity (PGA), which is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED). PGA type 1 presents in childhood with at least two of the following manifestations: candidiasis, hypoparathyroidism, or Addison disease. Cataracts, uveitis, alopecia, vitiligo, or autoimmune thyroid disease may also develop. Fat malabsorption occurs in 20% of patients with PGA-1 and may present as weight loss; diarrhea; or malabsorption of vitamin D, a fat-soluble vitamin used to treat the hypoparathyroidism. The fat malabsorption may be due to a deficiency in the jejunal enteroendocrine cells that produce cholecystokinin, causing a reduction in bile acid secretion. Hypoparathyroidism can also occur in systemic lupus erythematosus, caused by antiparathyroid antibodies.

Parathyroid deficiency may also be the result of damage from heavy metals such as copper (Wilson disease) or iron (hemochromatosis, transfusion hemosiderosis), granulomas, Riedel thyroiditis, tumors, or infection.

Functional hypoparathyroidism may also occur as a result of magnesium deficiency (malabsorption, chronic alcoholism), which prevents the secretion of PTH. Correction of hypomagnesemia results in rapid disappearance of phosphate and bicarbonate by the renal tubule. All of these actions cause a net increase in serum calcium.

HYPOPARATHYROIDISM & PSEUDOHYPOPARATHYROIDISM

Essentials of diagnosis

- Tetany, carpopedal spasms, tingling of lips and hands, muscle and abdominal cramps, psychological changes.
- Positive Chvostek sign and Trousseau phenomenon.
- Serum calcium low; serum phosphate high; alkaline phosphatase normal; urine calcium excretion reduced.
- Low or low-normal serum PTH in presence of hypocalcemia.
- Serum magnesium may be low.
of the condition. Hypermagnesemia can also suppress PTH secretion; it may occur in patients with kidney disease who take magnesium supplements, laxatives, or antacids.

In **congenital hypoparathyroidism**, parathyroid cells have calcium-sensing receptors (CaSR) that sense the serum calcium concentration and suppress PTH secretion by way of G-protein-coupled mechanisms. Gain-of-function mutations (constitutive activation) of the CaSR gene suppress the parathyroid glands, resulting in hypocalcemia without elevations in serum PTH levels. Such mutations cause "autosomal dominant hypocalcemia with hypercalciuria" from deficient secretion of PTH. The prevalence of autosomal dominant hypocalcemia with hypercalciuria in the population is about 1 in 70,000, and it typically presents in infancy with hypocalcemic seizures.

Hypoparathyroidism, deafness, and renal dysplasia (HDR or Barakat) syndrome is an autosomal dominant condition caused by haploinsufficiency or mutations of the gene **GATA3**; the condition is autosomal dominant. Hypocalcemia is present from birth but may not be detected until the occurrence of mental retardation or hypocalcemic tetany. Hypoparathyroidism may also be seen in DiGeorge syndrome, along with congenital cardiac and facial anomalies; hypocalcemia usually presents with tetany in infancy, but some cases are not detected until adulthood.

Familial isolated hypoparathyroidism is caused by mutations in various genes that encode the secretion of PTH or the embryologic development of the parathyroid glands. Mutations in the **TBCE** gene cause autosomal recessive hypoparathyroidism with other phenotypic abnormalities that are known as the Kenny-Caffey syndrome or the Sanjad-Sakati syndrome. Various mutations in genes that encode mitochondria have maternal inheritance and cause hypoparathyroidism in association with other syndromes: Kearns-Sayre (ophthalmoplegia, retinopathy, cardiomyopathy, diabetes) and MELAS (mitochondrial encephalopathy, lactic acidosis, stroke).

**Clinical Findings**

**A. Symptoms and Signs**

Acute hypoparathyroidism and hypocalcemia can occur spontaneously or may be precipitated when a patient with untreated hypoparathyroidism receives a proton pump inhibitor. Manifestations of hypocalcemia include tetany, muscle cramps, carpopedal spasm, irritability, altered mental status, convulsions, and stridor; tingling of the circumoral area, hands, and feet is almost always present. Symptoms of the chronic disease are lethargy, personality changes, anxiety state, blurring of vision due to premature cataracts, Parkinsonism, and mental retardation. Some patients with chronic hypocalcemia are asymptomatic, even with very low levels of serum calcium.

Chvostek sign (facial muscle contraction on tapping the facial nerve in front of the ear) is positive, and Trousseau phenomenon (carpal spasm after application of a sphygmomanometer cuff) is present. Cataracts may occur; the nails may be thin and brittle; the skin is dry and scaly; at times with fungus infection (candidiasis), and there may be loss of eyebrows; and deep tendon reflexes may be hyperactive. Papilledema and elevated cerebrospinal fluid pressure are occasionally seen. Teeth may be defective if the onset of the disease occurs in childhood.

**B. Laboratory Findings**

Serum calcium is low, serum phosphate high, urinary calcium low, and alkaline phosphatase normal. Serum calcium is largely bound to albumin. In hypalbuminemia, the serum ionized calcium may be determined, but it has had surprisingly poor clinical utility. Alternatively, the serum calcium level can be corrected for serum albumin level as follows:

\[
\text{"Corrected" serum Ca}^{2+} = \text{Serum Ca}^{2+} \text{ mg/dL} + (0.8 \times [4.0 - \text{Albumin g/dL}])
\]

PTH levels are low. Hypomagnesemia may exacerbate symptoms and decrease parathyroid function.

**C. Imaging**

Radiographs or CT scans of the skull may show basal ganglia calcifications; the bones may be denser than normal. Cutaneous calcification may occur.

**D. Other Examinations**

Slit-lamp examination may show early lenticular cataract formation. The electrocardiogram (ECG) shows prolonged QT intervals and T wave abnormalities. Patients with chronic hypoparathyroidism tend to have increased bone mineral density, particularly in the lumbar spine.

**Complications**

Acute tetany with stridor, especially if associated with vocal cord palsy, may lead to respiratory obstruction requiring tracheostomy. Pseudotumor cerebri has been reported. Congestive heart failure may rarely occur. The complications of chronic hypoparathyroidism largely depend on the duration of the disease. There may be associated autoimmunity causing sprue syndrome, pernicious anemia, or Addison disease. In long-standing cases, cataract formation and calcification of the basal ganglia are seen. Occasionally, parkinsonian symptoms or choreoarthithesis develop. Ossification of the paravertebral ligaments may occur with nerve root compression; surgical decompression may be required. Seizures are common in untreated patients. Over treatment with vitamin D and calcium may produce nephrocalcinosis and impairment of kidney function. Chronic hypocalcemia can cause heart failure.

**Differential Diagnosis**

Paresthesias, muscle cramps, or tetany due to respiratory alkalosis, in which the serum calcium is normal, can be confused with hypocalcemia. In fact, hyperventilation tends to accentuate hypocalcemic symptoms.

At times hypoparathyroidism is misdiagnosed as idiopathic epilepsy, choreoarthithesis, or brain tumor (on the basis of brain calcifications, convulsions, choked disks) or, more rarely, as "asthma" (on the basis of stridor and dyspnea).
In patients with hypoalbuminemia, serum levels of ionized calcium are normal. Hypocalcemia may also be due to malabsorption of calcium, magnesium, or vitamin D; patients do not always have diarrhea. Hypocalcemia may also be caused by certain drugs: loop diuretics, plicamycin, phenytoin, alendronate, and foscarnet. In addition, hypocalcemia may be seen in cases of rapid intravascular volume expansion or due to chelation from transfusions of large volumes of citrated blood. It is also observed in patients with acute pancreatitis. Hypocalcemia may develop in some patients with certain osteoblastic metastatic carcinomas (especially breast, prostate) instead of the expected hypercalcemia. Hypocalcemia with hyperphosphatemia (simulating hypoparathyroidism) is seen in azotemia but may also be caused by large doses of intravenous, oral, or rectal phosphate preparations and by chemotherapy of responsive lymphomas or leukemias.

Hypocalcemia with hypercalciuria may be due to a familial syndrome involving a mutation in the calcium-sensing receptor; such patients have levels of serum PTH that are in the normal range, distinguishing it from hypoparathyroidism. It is transmitted as an autosomal dominant disorder. Such patients are hypercalcemic; treatment with calcium and vitamin D may cause nephrocalcinosis.

Congenital pseudohyoparathyroidism is a group of disorders characterized by resistance to PTH. There are several subtypes caused by different mutations involving the PTH receptor or its G protein or adenylyl cyclase. Renal tubular resistance to PTH causes hypercalciuria with resultant hypocalcemia. PTH levels are high and the PTH receptors in bone are typically not involved, such that bony changes of hyperparathyroidism may be evident. In pseudohyoparathyroidism type 1a, patients have hypocalcemia and hyperphosphatemia with additional features known as Albright hereditary osteodystrophy: mental retardation, short stature, obesity, round face, short fourth metacarpals, ectopic bone formation, hypothyroidism, and hypogonadism. Patients without hypocalcemia but sharing the phenotypic abnormalities are said to have “pseudopseudohyoparathyroidism.”

Treatment
A. Emergency Treatment for Acute Attack (Hypoparathyroid Tetany)

This usually occurs after surgery and requires immediate treatment.

1. **Airway**—Be sure an adequate airway is present.

2. **Intravenous calcium gluconate**—Calcium gluconate, 10–20 mL of 10% solution intravenously, may be given **slowly** until tetany ceases. Ten to 50 mL of 10% calcium gluconate may be added to 1 L of 5% glucose in water or saline and administered by slow intravenous drip. The rate should be adjusted so that the serum calcium is maintained between 8 mg/dL and 9 mg/dL.

3. **Oral calcium**—Calcium salts should be given orally as soon as possible to supply 1–2 g of calcium daily. Liquid calcium carbonate, 500 mg/5 mL, may be especially useful. The dosage is 1–3 g calcium daily. Calcium citrate contains 21% calcium, but a higher proportion is absorbed with less gastrointestinal intolerance.

4. **Vitamin D preparations**—(Table 26–9.) Therapy should be started as soon as oral calcium is begun. The active metabolite of vitamin D, 1,25-dihydroxycholecalciferol (calcitriol), has a very rapid onset of action and is not long-lasting if hypercalcemia occurs. It is of great use in the treatment of acute hypocalcemia. Therapy is commenced at a dosage of 0.25 mcg orally each morning with upward dosage titration to near normocalcemia. Ultimately, doses of 0.5–2 mcg/d are usually required. Calcifediol (25-hydroxyvitamin D3), another option for treatment, has an intermediate onset and duration of action; the usual starting dose is 20 mcg/d orally.

5. **Magnesium**—If hypomagnesemia is present (chronic alcoholism, malnutrition, renal loss, drugs such as cisplatin, etc), it must be corrected to treat the resulting hypocalcemia. Acutely, magnesium sulfate is given intravenously, 1–2 g every 6 hours. Long-term magnesium replacement may be given as magnesium oxide tablets (600 mg), one or two per day, or as a combined magnesium and calcium preparation (CalMag, others).

6. **Transplantation of cryopreserved parathyroid tissue removed during prior surgery**—Transplantation restores normocalcemia in about 23% of cases.

B. **Maintenance Treatment**

The goal should be to maintain the serum calcium in a slightly low but asymptomatic range (8–8.6 mg/dL). This

| Table 26–9. Vitamin D preparations used in the treatment of hypoparathyroidism. |
|---|---|---|
| **Available Preparations** | **Daily Dose** | **Duration of Action** |
| Ergocalciferol ergosterol, (vitamin D2, Calciferol) | Capsules of 50,000 international units; 8000 international units/mL oral solution | 2000-200,000 units | 1-2 weeks |
| Cholecalciferol (vitamin D3) | Capsules of 50,000 international units not available commercially in United States; may be compounded | 10,000-50,000 units | 4-8 weeks |
| Calcitrol (Rocaltrol) | Capsules of 0.25 and 0.5 mcg; 1 mcg/mL oral solution; 1 mcg/mL for injection | 0.25-4 mcg | 5-2 weeks |
will minimize the hypercalciuria that would otherwise occur and provides a margin of safety against overdosage and hypercalcemia, which may produce permanent damage to kidney function. Patients with mild, asymptomatic hypocalcemia require no therapy. For others, calcium supplementation (1 g/d) is given, along with a vitamin D preparation.

Patients with chronic hypoparathyroidism must usually be treated with some type of vitamin D (Table 26–9). Monitoring of serum calcium at regular intervals (at least every 3 months) is mandatory. Calcitriol, a short-acting preparation, is given in doses that range from 0.25 mcg/d to 2.0 mcg orally daily. Ergocalciferol (vitamin D₂) is derived from plants and is commercially available. The usual dose ranges from 25,000 to 150,000 units/d. It is a slow-acting preparation that is stored in fat, giving it a long duration of action. If toxicity develops, hypercalcemia—treatable with hydration and prednisone—may persist for weeks after it is discontinued. Despite this risk, ergocalciferol usually produces a more stable serum calcium level than do the shorter-acting preparations.

Teriparatide (Forteo) is a recombinant preparation of human PTH 1-34. Teriparatide is effective in treating patients with hypoparathyroidism when given by subcutaneous injection at an initial dose of 0.4 mcg/kg twice daily. The dose is adjusted to produce normal serum calcium levels. The disadvantages of teriparatide therapy include its extremely high cost and the necessity for injections. Furthermore, teriparatide is not approved by the US Food and Drug Administration (FDA) for this indication because prolonged high doses in rats caused osteosarcoma. Therefore, teriparatide therapy is reserved for patients with severe hypoparathyroidism that fails to respond to vitamin D.

Target serum calcium levels (albumin-corrected) should be 8.0–8.5 mg/dL; these levels are mildly low to avoid hypercalcemia. It is prudent to monitor urine calcium with “spot” urine determinations and keep the level below 30 mg/dL if possible. Hypercalciuria may respond to oral hydrochlorothiazide, usually given with a potassium supplement.

Caution: Phenothiazine drugs should be administered with caution, since they may precipitate extrapyramidal symptoms in hypocalcemic patients. Furosemide should be avoided, since it may worsen hypocalcemia.

**Prognosis**

The outlook is good if the diagnosis is made promptly and treatment instituted. Any dental changes, cataracts, and brain calcifications are permanent. Periodic blood chemical evaluation is required, since changes in calcium levels may call for modification of the treatment schedule. Hypercalcemia that develops in patients with seemingly stable, treated hypoparathyroidism may be a presenting sign of Addison disease.

Despite optimal therapy, patients with hypoparathyroidism have been reported to have an overall reduced quality of life. Affected patients have a high risk of having mood and psychiatric disorders along with a reduced overall sense of well-being.

---

**HYPERPARATHYROIDISM**

**ESSENTIALS OF DIAGNOSIS**

- Frequently detected incidentally by screening.
- Renal calculi, polyuria, hypertension, constipation, fatigue, mental changes.
- Bone pain; rarely, cystic lesions and pathologic fractures.
- Serum and urine calcium elevated; urine phosphate high with low to normal serum phosphate; alkaline phosphatase normal to elevated.
- Elevated PTH.

**General Considerations**

Primary hyperparathyroidism is the most common cause of hypercalcemia, with a prevalence of 1–4 cases per 1000 persons. It occurs at all ages but most commonly in the seventh decade and in women (74%). Before age 45, the prevalence is similar in men and women.

The disease is caused by hypersecretion of PTH, usually by a single parathyroid adenoma (80%), and less commonly by hyperplasia by two or more parathyroid glands (20%), or carcinoma (≤ 1%). However, when hyperparathyroidism presents before age 30 years, there is a higher incidence of multinodular disease (36%) and parathyroid carcinoma (5%). The size of the parathyroid adenoma correlates with the serum PTH level.

Hyperparathyroidism is familial in about 10% of cases. Parathyroid hyperplasia may arise in MEN types 1, 2A, and 2B. In MEN 1, multinodular hyperparathyroidism is usually the initial manifestation and ultimately occurs in 90% of affected individuals. Hyperparathyroidism in MEN 2A is less frequent that in MEN 1 and is usually...
milder. Familial hyperparathyroidism can also occur in the hyperparathyroidism—jaw tumor syndrome, a rare autosomal dominant familial condition in which parathyroid cystic adenomas or carcinomas are associated with ossifying fibromas of the mandible and maxilla as well as renal lesions (cysts, hamartomas, Wilms tumors). Affected individuals usually present with severe hypercalcemia as teenagers or young adults; the pathology is usually a single parathyroid adenoma. (See Table 26–17.)

Hyperparathyroidism results in the excessive excretion of calcium and phosphate by the kidneys. PTH stimulates renal tubular reabsorption of calcium; however, hyperparathyroidism causes hypercalcemia and an increase in calcium in the glomerular filtrate that overwhelms tubular reabsorption capacity, resulting in hypercalcuria. At least 5% of renal calculi are associated with this disease. Diffuse parenchymal calcification (nephrocalcinosis) is seen less commonly. Excessive PTH can cause cortical demineralization that is particularly evident at the wrist and hip; trabecular bone is usually spared as evidenced by relatively higher spinal bone density compared to the wrist. Severe, chronic hyperparathyroidism can cause diffuse demineralization, pathologic fractures, and cystic bone lesions throughout the skeleton, a condition known as osteitis fibrosa cystica.

In chronic kidney disease, hyperphosphatemia and decreased renal production of 1,25-dihydroxycholecalciferol (1,25(OH)2D3) initially produce a decrease in ionized calcium. The parathyroid glands are stimulated (secondary hyperparathyroidism) and may enlarge, becoming autonomous (tertiary hyperparathyroidism). The bone disease seen in this setting is known as renal osteodystrophy. Parathyroid hyperplasia in uremia can result in extremely high serum PTH levels that are associated with uremic vascular calcification. Hypercalcemia often occurs after kidney transplant.

Parathyroid carcinoma is a rare cause of hyperparathyroidism but is more common in patients with serum calcium levels \( \geq 14.0 \text{ mg/dL} \). About 50% of parathyroid carcinomas are palpable.

### Clinical Findings

**A. Symptoms and Signs**

In the developed world, hypercalcemia of hyperparathyroidism is typically discovered accidentally by routine chemistry panels. Many patients are asymptomatic or have mild symptoms that may be elicited only upon questioning. Parathyroid adenomas are usually so small and deeply located in the neck that they are almost never palpable; when a mass is palpated, it usually turns out to be an incidental thyroid nodule.

Symptomatic patients are said to have problems with “bones, stones, abdominal groans, psychic moans, with fatigue overtones.” The manifestations are categorized as skeletal, urinary tract, and those associated with hypercalcemia.

1. **Skeletal manifestations**—Hyperparathyroidism causes a loss of cortical bone and a gain of trabecular bone. Low bone density is typically most prominent at the wrist. Postmenopausal women are prone to asymptomatic vertebral fractures. Although significant bone demineralization is uncommon in mild hyperparathyroidism, osteitis fibrosa cystica may present as pathologic fractures or as “brown tumors” or cysts of the jaw. More commonly, patients have bone pain and arthralgias.

2. **Manifestations of hypercalcemia**—Mild hypercalcemia may be asymptomatic. However, hypercalcemia usually causes a variety of manifestations whose severity is not entirely predictable by the level of serum calcium or PTH in patients with hyperparathyroidism. In fact, patients with only mild hypercalcemia can have significant symptoms, particularly depression, constipation, and bone and joint pain. Paresthesias, muscular weakness, and diminished deep tendon reflexes are examples of neurovascular manifestations. Central nervous system manifestations include malaise, fatigue, intellectual weariness, depression, increased sleep requirement, progressing to cognitive impairment, disorientation, psychosis, or stupor. Cardiovascular symptoms include hypertension, prolonged P-R interval, shortened Q-T interval, sensitivity to arrhythmic effects of digitalis, bradyarrhythmias, heart block, and asystole. Renal manifestations include polyuria and polydipsia, caused by hypercalcemia-induced nephrogenic diabetes insipidus. Among all patients with newly discovered hyperparathyroidism, calcium-containing kidney stones have occurred or are detectable in about 18%. Patients with asymptomatic hyperparathyroidism have a 7% incidence of asymptomatic calcium nephrolithiasis, compared to 1.6% incidence in age-matched controls. Gastrointestinal symptoms include anorexia, nausea, vomiting, abdominal pain, weight loss, constipation, and obstruction. Pancreatitis occurs in 3%. **Pruritus** may be present. Calcium may precipitate in the corneas (“band keratopathy”). Calcium may also precipitate in extravascular tissues as well as in small arteries, causing small vessel thrombosis and skin necrosis (calciphylaxis).

3. **Hyperparathyroidism during pregnancy**—About 67% of women with primary hyperparathyroidism during pregnancy experience complications such as nephrolithiasis, hyperemesis, pancreatitis, muscle weakness, cognitive changes, and hypercalcemic crisis. About 80% of fetuses experience complications of maternal hyperparathyroidism, including fetal demise, preterm delivery, low birth weight, postpartum neonatal tetany, and permanent hypoparathyroidism.

**B. Laboratory Findings**

The hallmark of primary hyperparathyroidism is hypercalcemia, with the serum adjusted total calcium \( > 10.5 \text{ mg/dL} \) (Figure 26–1). The adjusted total calcium = measured serum calcium in mg/dL + \( [0.8 \times (4.0 – \text{patient’s serum albumin in g/dL})] \). Serum ionized calcium determinations have not proven very helpful clinically, except in hyperproteinemic states (such as hyperalbuminemia, Waldenström macroglobulinemia, myeloma, or thrombocythemia); in such patients with hyperparathyroidism, the serum ionized calcium is usually \( > 5.4 \text{ mg/dL} \). (1.4 mmol/L).
C. Imaging

Preoperative sestamibi-iodine subtraction scanning and neck ultrasonography can locate parathyroid adenomas preoperatively in an effort to improve the outcome and limit the invasiveness of neck surgery. Parathyroid imaging is crucial for patients who have had prior neck surgery. However, the usefulness of preoperative parathyroid localizing imaging studies for first neck explorations remains controversial. Preoperative scanning does not improve the outcome of initial bilateral neck explorations performed by a surgeon with special expertise in parathyroid surgery. Therefore, preoperative imaging has been used mainly to improve the outcome for limited neck exploration, with only modest success. (See Surgery.) Imaging is not useful for the diagnosis of hyperparathyroidism, which must be made by serum calcium and PTH determinations. Small benign thyroid nodules are discovered incidentally in nearly 50% of patients with hyperparathyroidism who have imaging with ultrasound or MRI.
CT and MRI scanning of the neck are not ordinarily required or useful for initial preoperative parathyroid localizing studies, since these scanning techniques are less sensitive for identifying tiny parathyroid adenomas. However, for repeat neck operations and when ectopic parathyroid glands are suspected, MRI is preferred since it offers better soft tissue contrast than CT scanning and is less adversely affected by postoperative changes in the neck.

Patients with hyperparathyroidism have a high risk of calcium nephrolithiasis. Therefore, it has been suggested that all patients with hyperparathyroidism have noncontrast-enhanced CT scanning of the kidneys to determine whether calcium-containing stones are present. For patients with apparently asymptomatic hyperparathyroidism, the presence or absence of calcium nephrolithiasis can be a deciding factor about whether to have parathyroidectomy surgery.

Bone density measurements by dual energy x-ray absorptiometry (DXA) are helpful in determining the amount of bone loss in patients with hyperparathyroidism. Bone loss occurs mostly in long bones, and DXA should ideally include three areas: lumbar spine, hip, and distal radius.

Bone radiographs are usually normal and are not required to make the diagnosis of hyperparathyroidism. There may be demineralization, subperiosteal resorption of bone (especially in the radial aspects of the fingers), or loss of the lamina dura of the teeth. There may be cysts throughout the skeleton, mottling of the skull (“salt-and-pepper appearance”), or pathologic fractures. Articular cartilage calcification (chondrocalcinosis) is sometimes found.

Patients with renal osteodystrophy may have ectopic calcifications around joints or in soft tissue. Such patients may exhibit radiographic changes of osteopenia, osteitis fibrosa, or osteosclerosis, alone or in combination. Osteosclerosis of the vertebral bodies is known as “rugger jersey spine.”

### Complications

Pathologic long bone fractures are more common in patients with hyperparathyroidism than in the general population. Urinary tract infection due to stone and obstruction may lead to kidney disease and uremia. If the serum calcium level rises rapidly, clouding of sensorium, kidney disease, and rapid precipitation of calcium throughout the soft tissues may occur. Peptic ulcer and pancreatitis may be intractable before surgery. Insulinomas or gastrinomas may be associated, as well as pituitary tumors (MEN type 1). Pseudogout may complicate hyperparathyroidism both before and after surgical removal of tumors. Hypercalcemia during gestation produces neonatal hypercalcemia.

In tertiary hyperparathyroidism due to chronic kidney disease, high serum calcium and phosphate levels may cause disseminated calcification in the skin, soft tissues, and arteries (calciﬁphaxis); this can result in painful ischemic necrosis of skin and gangrene, cardiac arrhythmias, and respiratory failure. The actual serum levels of calcium and phosphate have not correlated well with calciﬁphaxis, but a calcium (mg/dL) × phosphate (mg/dL) product over 70 is usually present.

### Differential Diagnosis

#### A. Artifact

A report of hypercalcemia may be due to laboratory error or excess tourniquet time and should always be repeated. Hypercalcemia may be due to high serum protein concentrations; in the presence of very high or low serum albumin concentrations, a serum ionized calcium is more dependable than the total serum calcium concentration. Hypercalcemia may also be seen with dehydration; spurious elevations in serum calcium have been reported with severe hypertriglyceridemia, when the calcium assay uses spectrophotometry.

#### B. Hypercalcemia of Malignancy

Many malignant tumors (breast, lung, pancreas, uterus, hypernephroma, parangangioma, etc.) can produce hypercalcemia. In some cases (breast carcinoma especially), bony metastases are present. In others, no metastases to bone can be demonstrated. Most of these tumors secrete PTH-related protein (PTHrP), which has tertiary structural homologies to PTH and causes bone resorption and hypercalcemia similar to those of PTH. The clinical features of the hypercalcemia of cancer can closely simulate hyperparathyroidism. Serum phosphate is often low, but the plasma level of PTH is low. Serum PTHrP may be elevated.

**Multiple myeloma** is a common cause of hypercalcemia in the older population. Many other hematologic cancers, such as monomyelocytic leukemia, T cell leukemia and lymphoma, and Burkitt lymphoma, have also been associated with hypercalcemia. Multiple myeloma causes kidney dysfunction; resultant increased levels of carboxyl terminal PTH may cause it to be confused with hyperparathyroidism if a carboxyl terminal PTH assay is used.

#### C. Sarcoidosis and Other Granulomatous Disorders

Macrophages and perhaps other cells present in granulomatous tissue have the ability to synthesize 1,25(OH)2D3. Hypercalcemia has been reported in patients with sarcoidosis, tuberculosis, berylliosis, histoplasmosis, coccidiodomycosis, leprosy, and even foreign-body granuloma. Increased intestinal calcium absorption and hypercalciuria are more common than hypercalcemia. Serum levels of 1,25(OH)2D3 are elevated. Sarcoid granulomas can also secrete PTHrP.

#### D. Calcium or Vitamin D Ingestion

Ingestion of large amounts of calcium or vitamin D can cause hypercalcemia, especially in patients who concurrently take thiazide diuretics, which reduce urinary calcium loss. Hypercalcemia is reversible following withdrawal of calcium and vitamin D supplements. If hypercalcemia persists, the possibility of associated hyperparathyroidism should be strongly considered.

In vitamin D intoxication, patients may be taking large amounts of vitamin D for unclear reasons, so a thorough review of all medications is important. Hypercalcemia may persist for several weeks. Serum levels of 25-hydroxycholecalciferol (25(OH)D3) are helpful to confirm the
diagnosis. A brief course of corticosteroid therapy may be necessary if hypercalcemia is severe.

E. Familial Benign Hypocalciuric Hypercalcemia

Familial benign hypocalciuric hypercalcemia can be easily mistaken for mild hyperparathyroidism. It is a common autosomal dominant inherited disorder (prevalence: 1 in 16,000) caused by a loss-of-function mutation in the gene encoding the CaSR. CaSRs are found on the surface of the parathyroid glands and allow the parathyroid glands to vary PTH secretion according to serum calcium levels. Reduced function of the CaSR causes the parathyroid glands to falsely “sense” hypercalcemia and inappropriately release slightly excessive amounts of PTH. At the same time, the renal tubule CaSRs are also affected, causing hypocalciuria. Familial benign hypocalciuric hypercalcemia is characterized by hypercalcemia, hypocalciuria (usually < 50 mg/24 h), variable hypermagnesemia, and normal or minimally elevated levels of PTH. These patients do not normalize their hypercalcemia after subtotal parathyroid removal and should not be subjected to surgery. The condition has an excellent prognosis and is easily diagnosed with a family history and urinary calcium clearance determination.

F. Vitamin D Deficiency

Secondary hyperparathyroidism predictably develops in patients with a deficiency in vitamin D. Serum calcium levels are typically in the normal range, but may rise to become borderline elevated with time, due to parathyroid glandular hyperplasia. (See Osteomalacia section.)

G. Adrenal Insufficiency

Hypercalcemia is common in untreated Addison disease. This is partly due to disinhibition of calcium uptake by the renal tubule and gut. Additionally, Addison disease can cause dehydration and hyperproteinemia, resulting in higher levels of nonionized calcium.

H. Immobilization Hypercalcemia

Prolonged immobilization at bed rest commonly causes hypercalcemia, particularly in adolescents, critically ill patients, and patients with extensive Paget disease of bone. Hypercalcemia develops in about one-third of acutely ill patients being treated in intensive care units, particularly patients with acute kidney injury. Serum calcium elevations are typically mild but may reach 15 mg/dL. Serum PTH levels are usually slightly elevated, consistent with mild hyperparathyroidism, but may be suppressed or normal.

I. Other Causes of Hypercalcemia

Other causes of hypercalcemia are shown in Table 21–8. Modest hypercalcemia is occasionally seen in patients taking thiazide diuretics or lithium; such patients may have an inappropriately nonsuppressed PTH level with hypercalcemia. Hypercalcemia occurs frequently in infants with Williams syndrome. Hyperthyroidism causes increased turnover of bone and occasional hypercalcemia. Bisphosphonates can increase serum calcium in 20% and serum PTH becomes high in 10%, mimicking hyperparathyroidism.

Treatment

A. Asymptomatic Primary Hyperparathyroidism

Patients with mild asymptomatic hyperparathyroidism may not need therapy. Such patients are advised to keep active, avoid immobilization, and drink adequate fluids. For postmenopausal women with hyperparathyroidism, estrogen replacement therapy reduces serum calcium by an average of 0.75 mg/dL and slightly improves bone density.

Affected patients must avoid thiazide diuretics, large doses of vitamin A, and calcium-containing antacids or supplements. Serum calcium and albumin are checked about twice yearly, kidney function and urine calcium once yearly, and three-site bone density (distal radius, hip, and spine) every 2 years. Rising serum calcium should prompt further evaluation and determination of PTH levels.

B. Surgical Parathyroidectomy

Parathyroidectomy is recommended for patients with symptomatic hyperparathyroidism, kidney stones, bone disease, and pregnancy.

Some patients with seemingly asymptomatic hyperparathyroidism may be surgical candidates for other reasons such as (1) serum calcium 1 mg/dL (0.25 mmol/L) above the upper limit of normal with urine calcium excretion > 50 mg/24 h (off thiazide diuretics), (2) urine calcium excretion over 400 mg/24 h, (3) creatinine clearance < 60 mL/min, (4) cortical bone density (wrist, hip) ≥ 2.5 SD below normal or previous fragility bone fracture, (5) relative youth (under age 50–60 years), (6) difficulty ensuring medical follow-up, or (7) pregnancy. During pregnancy, parathyroidectomy is performed in the second trimester. Surgery for patients with “asymptomatic” hyperparathyroidism may confer modest benefits in social and emotional function, with improvements in anxiety and phobias being reported in comparison to similar patients who are monitored without surgery.

Preoperative parathyroid imaging has been used in an attempt to allow unilateral minimally invasive neck surgery. The reported success rates vary considerably. The usefulness of preoperative parathyroid imaging was evaluated in a series of 350 patients with sporadic primary hyperparathyroidism. A single gland was predicted by sestamibi in 83%, by ultrasound in 85%, and by concordance of both in 59% of patients. Unilateral neck exploration, directed by these studies, resulted in success rate of only 73%, 77%, and 82%, respectively, despite the intraoperative quick PTH assay predicting success. Even in patients with concordant sestamibi and ultrasound scans, and an intraoperative PTH drop of > 50%, at least one additional abnormal parathyroid gland is left behind in the contralateral neck in 15% of patients.

Without preoperative localization studies, bilateral neck exploration is usually advisable for the following:
(1) patients with a family history of hyperparathyroidism, (2) patients with a personal or family history of MEN, and (3) patients wanting an optimal chance of success with a single surgery. Patients undergoing unilateral neck exploration can have the incision widened for bilateral neck exploration if two abnormal glands are found or if the serum quick PTH falls by < 50% within 10 minutes of the parathyroid resection. Parathyroid glands are not uncommonly supernumerary (five or more) or ectopic (eg, intrathyroidal, carotid sheath, mediastinum). The optimal surgical management for patients with MEN type 1 is subtotal parathyroidectomy that usually results in a cure, although recurrent hyperparathyroidism develops in 18% and the rate of postoperative hypoparathyroidism is high.

**Parathyroid hyperplasia** is commonly seen with secondary or tertiary hyperparathyroidism associated with uremia. Cinacalcet is an alternative to surgery. When surgery is performed, a subtotal parathyroidectomy is optimal; three and one-half glands are usually removed, and a metal clip is left to mark the location of residual parathyroid tissue.

**Parathyroid carcinoma** can cause severe hypercalcemia associated with very high serum levels of PTH. Preoperative localizing studies usually detect a large invasive tumor. Therapy consists of en bloc resection of the tumor and the ipsilateral thyroid lobe. Metastases to local and to distant sites occur in about 50% of patients. Reoperation for neck recurrence is usually necessary. Adjuvant treatment includes radiation therapy. Cinacalcet is administered initially in doses of 30 mg twice daily and increased as needed up to 90 mg four times daily. Intravenous bisphosphonate (zoledronic acid) is used as needed.

**Complications**—Serum PTH levels fall below normal in 70% of patients within hours after successful surgery, commonly causing hypocalcemic paresthesias or even tetany. Hypocalcemia tends to occur the evening after surgery or on the next day. Therefore, frequent postoperative monitoring of serum calcium (or serum calcium plus albumin) is advisable beginning the evening after surgery. Once hypercalcemia has resolved, liquid or chewable calcium carbonate is given orally to reduce the likelihood of hypocalcemia. Symptomatic hypocalcemia is treated with larger doses of calcium; calcitriol (0.25–1 mcg daily orally) may be added, with the dosage depending on symptom severity. Magnesium salts are sometimes required postoperatively, since adequate magnesium is required for functional recovery of the remaining suppressed parathyroid glands.

In about 12% of patients having successful parathyroid surgery, PTH levels rise above normal (while serum calcium is normal or low) by 1 week postoperatively. This secondary hyperparathyroidism is probably due to “hungry bones” and is treated with calcium and vitamin D preparations. Such therapy is usually needed only for 3–6 months but is required long-term by some patients.

Hyperparathyroidism commonly occurs immediately following parathyroid surgery. It is caused by release of stored thyroid hormone during surgical manipulation of the thyroid. In symptomatic patients, short-term treatment with propranolol may be required for several days.

### C. Medical Measures

1. **Fluids**—Hypercalcemia is treated with a large fluid intake unless contraindicated. Severe hypercalcemia requires hospitalization and intensive hydration with intravenous saline. (See Chapter 21.)

2. **Bisphosphonates**—Intravenous bisphosphonates are potent inhibitors of bone resorption and can temporarily treat the hypercalcemia of hyperparathyroidism. Pamidronate in doses of 30–90 mg (in 0.9% saline) is administered intravenously over 2–4 hours. Zoledronic acid 2–4 mg is administered intravenously over 15 to 20 minutes. These drugs cause a gradual decline in serum calcium over several days that may last for weeks to months. Such intravenous bisphosphonates are used generally for patients with severe hyperparathyroidism in preparation for surgery. Oral bisphosphonates, such as alendronate, are not effective for treating the hypercalcemia or hypercalciuria of hyperparathyroidism. However, oral alendronate has been shown to improve bone mineral density in the lumbar spine and hip (not distal radius) and may be used for asymptomatic patients with hyperparathyroidism who have a low bone mineral density.

3. **Vitamin D and vitamin D analogs**—

   **A. Primary hyperparathyroidism**—For patients with vitamin D deficiency, careful vitamin D replacement may be beneficial to patients with hyperparathyroidism. Aggravation of hypercalcemia does not ordinarily occur. Serum PTH levels may fall with vitamin D replacement in doses of 800–2000 international units daily. Occasionally, larger doses are required to achieve normal 25-OH vitamin D levels.

   **B. Secondary and tertiary hyperparathyroidism associated with azotemia**—Calcitriol, given orally or intravenously after dialysis, suppresses parathyroid hyperplasia of kidney disease. For patients with normal serum calcium levels, it is given orally in starting doses of 0.25 mcg on alternate days or daily. Calcitriol often causes hypercalcemia, so that serum levels of calcium and phosphate must be monitored to ensure that the serum Ca2+ × PO4 product remains ≤ 70. When that occurs, the dose of calcitriol is decreased or the patient is switched to therapy with vitamin D analogs or cinacalcet.

   The vitamin D analogs paricalcitol and doxercalciferol suppress PTH secretion and cause less hypercalcemia than calcitriol; however, they are very expensive. The doses are adjusted to keep serum PTH levels between 150 pg/mL and 300 pg/mL. Paricalcitol (Zemplar) is administered intravenously during dialysis three times weekly in starting doses of 0.04–0.1 mcg/kg to a maximum dose of 0.24 mcg/kg three times weekly. Alternatively, paricalcitol may be administered orally at doses of 1–2 mcg daily for serum PTH levels < 500 pg/mL or 2–4 mcg daily for serum PTH levels > 500 pg/mL. Dialysis patients receiving paricalcitol have improved survival compared with patients receiving calcitriol. Doxercalciferol (Hectorol) is administered intravenously three times weekly during hemodialysis to patients with azotemic secondary hyperparathyroidism in starting doses of 4 mcg three times weekly to a maximum dose of 18 mcg three times weekly. Alternatively, doxercalciferol may be administered orally three times weekly at dialysis,
starting with 10 mcg three times weekly at dialysis to a maximum of 60 mcg/wk.

4. Cinacalcet—Cinacalcet hydrochloride is a calcimimetic agent that binds to sites of the parathyroid glands’ extracellular CaSRs to increase the glands’ affinity for extracellular calcium, thereby decreasing PTH secretion. About 50% of azotemic patients with secondary or tertiary hyperparathyroidism are resistant to vitamin D analogs (see above). Cinacalcet is given orally in starting doses of 30 mg daily to a maximum of 250 mg daily, with dosage adjustments to keep the serum PTH in the range of 150–300 pg/mL. Patients with primary hyperparathyroidism have also been treated successfully with cinacalcet in oral doses of 30–50 mg twice daily, with 73% of patients achieving normocalcemia. Cinacalcet is given to patients with severe hypercalcemia due to parathyroid carcinoma at initial doses of 30 mg orally twice daily and increased progressively to 60 mg twice daily, then 90 mg twice daily to a maximum of 90 mg every 6–8 hours. Cinacalcet is usually well tolerated but may cause nausea and vomiting, which are usually transient. It is very expensive.

5. Other measures—Estrogen replacement, given to postmenopausal women, reduces hypercalcemia slightly. Similarly, raloxifene also reduces the hypercalcemia of hyperparathyroidism, reducing serum calcium levels an average of 0.4 mg/dL. Propranolol may be useful for preventing the adverse cardiac effects of hypercalcemia.

Renal osteodystrophy is caused by secondary or tertiary hyperparathyroidism during kidney disease. It can be prevented or delayed by reducing hyperphosphatemia with phosphate binding medication and dietary phosphate restriction.

► Prognosis

Patients with symptomatic hyperparathyroidism usually experience worsening disease (eg, nephrolithiasis) unless they have treatment. Conversely, the majority of completely asymptomatic patients with mild hypercalcemia (serum calcium <11.0 mg/dL) remain stable with follow-up. However, worsening hypercalcemia, hyperphosphatemia, and reductions in cortical bone mineral density develop in about one-third of asymptomatic patients. Therefore, asymptomatic patients must be monitored carefully and treated with oral hydration and mobilization.

Surgical removal of apparently single sporadic parathyroid adenomas is successful in 94%. Patients with MEN 1 undergoing subtotal parathyroidectomy may experience long remissions, but hyperparathyroidism frequently recurs. Despite treatment for hyperparathyroidism, patients remain at increased risk for all-cause mortality, cardiovascular disease, kidney stones, and renal failure. These increased risks are likely the residuals of pretreatment hypertension and nephrolithiasis.

Spontaneous cure due to necrosis of the tumor has been reported but is exceedingly rare. The bones, in spite of severe cyst formation, deformity, and fracture, will heal if a parathyroid tumor is successfully removed. The presence of pancreatitis increases the mortality rate. Acute pancreatitis usually resolves with correction of hypercalcemia, whereas subacute or chronic pancreatitis tends to persist. Significant renal damage may progress even after removal of an adenoma.

Parathyroid carcinoma tends to invade local structures and may sometimes metastasize; repeat surgical resections and radiation therapy can prolong life. Aggressive surgical and medical management of parathyroid carcinoma can result in a median overall survival of 14.3 years (range 10.5–25.7 years) from the date of diagnosis. Factors associated with a worsened mortality rate include lymph node or distant metastases, high number of recurrences, and higher serum calcium levels at recurrence.

METABOLIC BONE DISEASE

The term “metabolic bone disease” denotes those conditions producing diffusely decreased bone density and diminished bone strength. It is categorized by histologic appearance: osteoporosis (bone matrix and mineral both decreased) and osteomalacia (bone matrix intact, mineral decreased). Osteoporosis and osteomalacia often coexist in the same patient.

OSTEOPOROSIS

► Fracture propensity of spine, hip, pelvis, and wrist from demineralization.

► Serum PTH, calcium, phosphorus, and alkaline phosphatase usually normal.

► Serum 25-hydroxyvitamin D levels often low as a comorbid condition.
**General Considerations**

Osteoporosis is a skeletal disorder characterized by a loss of bone osteoid that reduces bone integrity, resulting in an increased risk of fractures. In the United States, osteoporosis causes about 2 million fractures annually, including 547,000 vertebral fractures, 300,000 hip fractures, and 135,000 pelvic fractures. White women have a 40% lifetime risk of sustaining one or more osteoporotic fractures. The morbidity and indirect mortality rates are very high. The rate of bone formation is often normal, whereas the rate of bone resorption is increased.

Osteoporosis can be caused by a variety of factors, which are listed in Table 26–10. The most common causes are aging; high-dose corticosteroid administration; alcoholism; and sex hormone deficiency, particularly menopause in women.

**Osteogenesis imperfecta** is caused by a major mutation in the gene encoding for type I collagen, the major collagen constituent of bone. This causes severe osteoporosis; spontaneous fractures occur in utero or during childhood. Blue sclerae may be present. Certain polymorphisms in the genes encoding type I collagen are common, particularly in whites, resulting in collagen disarray and predisposing to hypogonadal (eg, menopausal) or idiopathic osteoporosis.

**Clinical Findings**

**A. Symptoms and Signs**

Osteoporosis is usually asymptomatic until fractures occur. It may present as backache of varying degrees of severity or as a spontaneous fracture or collapse of a vertebra. Loss of height is common. Once osteoporosis is identified, a carefully directed history and physical examination must be performed to determine its cause (Table 26–10).

**B. Laboratory Findings**

Serum calcium, phosphate, and PTH are normal. The alkaline phosphatase is usually normal but may be slightly elevated, especially following a fracture. Vitamin D deficiency is very common and serum determination of 25-hydroxyvitamin D should be obtained for every individual with low bone density. Serum 25-hydroxyvitamin D levels below 20 ng/mL are considered frank vitamin D deficiency. Lesser degrees of vitamin D deficiency (serum 25-hydroxyvitamin D levels between 20 ng/mL and 30 ng/mL) may also increase the risk for hip fracture. (See Osteomalacia, below.) Testing for thyrotoxicosis and hypogonadism may be required. Celiac disease may be screened for with serum immunoglobulin A (IgA) endomysial antibody and tissue transglutaminase antibody determinations.

**C. Bone Densitometry**

DXA is used to determine the bone density of the lumbar spine and hip. Bone densitometry should be performed on all patients who are at risk for osteoporosis or osteomalacia or have pathologic fractures or radiographic evidence of diminished bone density. This test delivers negligible radiation, and the measurements are quite accurate. However, bone densitometry cannot distinguish osteoporosis from osteomalacia; in fact, both are often present. Also, the bone mineral density does not directly measure bone quality and is only fairly successful at predicting fractures. Vertebral bone mineral density may be misleadingly high in compressed vertebrae and in patients with extensive arthritis. DXA also overestimates the bone mineral density of taller persons and underestimates the bone mineral density of smaller persons. Quantitative CT delivers more radiation but is more accurate in the latter situations.

Bone mineral density in typically expressed in g/cm², for which there are different normal ranges for each bone and for each type of DXA-measuring machine. The “T score” is a simplified way of reporting bone density in which the patient’s bone mineral density is compared to the young normal mean and expressed as a standard deviation score. The World Health Organization has established criteria for defining osteoporosis in postmenopausal white women, based on T score:

- T score ≥ –1.0: Normal.
- T score –1.0 to –2.5: Osteopenia (“low bone density”).
- T score < –2.5: Osteoporosis.

This classification is somewhat arbitrary and there really is no bone mineral density fracture threshold; instead, the fracture risk increases about twofold for each standard deviation drop in bone mineral density. In fact, most women with fragility fractures have bone densities above –2.5. Surveillance DXA bone densitometry is recommended for postmenopausal women with a frequency according to their T scores: obtain DXA every 5 years for

*See Table 26–11 for causes of osteomalacia.*
Osteopenia and fractures can be caused by osteomalacia (see below) and bone marrow neoplasia such as myeloma or metastatic bone disease. These conditions coexist in many patients.

### Treatment

#### A. General Measures

For prevention and treatment of osteoporosis, the diet should be adequate in protein, total calories, calcium, and vitamin D. Pharmacologic corticosteroid doses should be reduced or discontinued if possible. Thiazides may be useful if hypercalciuria is present. High-impact physical activity (eg, jogging) significantly increases bone density in men and women. Stair-climbing increases bone density in women. Patients who cannot exercise vigorously should be encouraged to engage in other exercise regularly, thereby increasing strength and reducing the risk of falling. Weight training is helpful to increase muscle strength as well as bone density. Measures should be taken to avoid falls at home (eg, adequate lighting, handrails on stairs, handholds in bathrooms). Patients who have weakness or balance problems must use a cane or a walker; rolling walkers should have a brake mechanism. Balance exercises can reduce the risk of falls. Patients should be kept active; bedridden patients should be given active or passive exercises. The spine may be adequately supported (though braces or corsets are usually not well tolerated), but rigid or excessive immobilization must be avoided. Alcohol and smoking should be avoided.

#### B. Specific Measures

Several treatment options are available, so a regimen is tailored to each patient. Generally, treatment is indicated for all women with osteoporosis (T scores below –2.5) and for all patients who have had fragility fractures. Prophylactic treatment should also be considered for patients with advanced osteopenia (T scores between –2.0 and –2.5).

1. **Vitamin D and calcium**—Osteoporosis and osteomalacia often coexist (see Osteomalacia section). Sun exposure and vitamin D supplementation are useful in preventing and treating osteomalacia but not osteoporosis. Vitamin D supplementation reduces the incidence of vertebral fractures by 37% and may slightly reduce the incidence of nonvertebral fractures. Oral vitamin D is given in doses of 800-2000 international units daily. Vitamin D supplementation is especially required during winter months and for patients having prolonged hospitalization or nursing home care, for patients with serum levels of 25-hydroxyvitamin D below 20 ng/mL, and those with intestinal malabsorption.

Calcium supplementation does not reduce the fracture risk in otherwise healthy postmenopausal women. One meta-analysis concluded that calcium supplementation is associated with a 27% increased risk of myocardial infarction; however, methodologic shortcomings in that study have raised doubts about its validity. Conversely, the Women’s Health Initiative found that myocardial infarction rates were not significantly higher among postmenopausal women taking calcium. Calcium supplements may increase the risk of calcium-containing kidney stones, unless taken with meals. Some patients experience gastrointestinal upset with calcium supplements. Therefore, calcium supplementation should probably be given only to those patients whose diets are low in calcium. More important is the assurance of adequate vitamin D through sun exposure or oral vitamin D supplementation. If calcium supplementation is given, it should include vitamin D. Calcium supplementation may be given as calcium citrate (0.4–0.7 g elemental calcium per day) or calcium carbonate (1–1.5 g elemental calcium per day).

2. **Bisphosphonates**—Bisphosphonates all work similarly, inhibiting osteoclast-induced bone resorption. They increase bone density significantly and reduce the incidence of both vertebral and nonvertebral fractures. Bisphosphonates have also been effective in preventing corticosteroid-induced osteoporosis. To ensure intestinal absorption, oral bisphosphonates must be taken in the morning with at least 8 oz of plain water at least 40 minutes before consumption of anything else. The patient must remain upright after taking bisphosphonates to reduce the risk of esophagitis. These medications are excreted in the urine. However, no dosage adjustments are required for patients with creatinine clearances above 35 mL/min.

There has been little experience giving bisphosphonates to patients with severe kidney disease; if given, the dose would need to be greatly reduced and serum phosphate levels monitored.

Bisphosphonates may be given orally once monthly or weekly. Available oral preparations include alendronate, 70 mg orally once weekly (tablet or solution), and risendronate, 35 mg orally once weekly. Both these medications reduce the risk of both vertebral and nonvertebral fractures. Studies sponsored by the manufacturer of alendronate found that alendronate was significantly more potent than risendronate and equally well tolerated. Another bisphosphonate, ibandronate sodium, is taken once monthly in a dose of 150 mg orally. Once-monthly ibandronate is convenient and reduces the risk of vertebral fractures but not nonvertebral fractures; its effectiveness has not been directly compared with other bisphosphonates. Oral bisphosphonates can cause nausea, chest pain, and hoarseness. Erosive esophagus can occur, particularly in patients with hiatal hernia and gastroesophageal reflux.

For patients who cannot tolerate oral bisphosphonates or for whom oral bisphosphonates are contraindicated, intravenous bisphosphonates are available. Zoledronic acid is a third-generation bisphosphonate and a potent osteoclast inhibitor. It can be given every 12 months in doses of 2–4 mg intravenously over at least 15–30 minutes. Pamidronate can be given in doses of 30–60 mg by
slow intravenous infusion in normal saline solution every 3–6 months.

Bisphosphonate therapy can cause several side effects that are collectively known as the acute-phase response. Such a response occurs in 42% of patients following the first infusion of zoledronic acid and usually starts within the first few days following the infusion. Among patients receiving their first infusion of zoledronic acid, these adverse side effects have included fever, chills, or flushing (20%); musculoskeletal pain (20%); nausea, vomiting, or diarrhea (8%); nonspecific symptoms, such as fatigue, dyspnea, edema, headache, or dizziness (22%); and eye inflammation (0.6%). The acute-phase response is most commonly seen after the first dose of bisphosphonate (particularly zoledronic acid) and tends to diminish with time. Symptoms are transient, lasting several days and usually resolving spontaneously but typically recurring with subsequent doses. For patients experiencing a severe acute-phase response with zoledronic acid, intravenous pamidronate can substitute for zoledronic acid for subsequent treatment. Additionally, patients who experience an especially severe acute-phase response can be given prophylactic corticosteroids and ondansetron prior to subsequent bisphosphonate infusions.

Osteonecrosis of the jaw is a rare complication of bisphosphonate therapy for osteoporosis. A painful, necrotic, nonhealing lesion of the jaw occurs, particularly after tooth extraction. About 95% of jaw osteonecrosis cases have occurred with high-dose therapy with zoledronic acid or pamidronate for patients with myeloma or solid tumor osteolytic metastases. Only about 5% of cases have occurred in patients receiving oral (or, less frequently, intravenous) bisphosphonate doses for osteoporosis. The incidence of osteonecrosis is estimated to be about 1:100,000 patients treated for osteoporosis and 1:100 patients being treated for cancer. In a prospective 3-year trial of 7714 women who received intravenous zoledronic acid 5 mg/year, there were no cases of osteonecrosis. For patients with painful osteonecrotic exposed bone, treatment is 90% effective (without resolution of the exposed bone) using antibiotics along with 0.12% chlorhexidine antiseptic mouthwash. Patients receiving bisphosphonates must receive regular dental care and try to avoid dental extraction.

Atypical “chalkstick” fractures of the femur occur rarely in patients taking bisphosphonates. Bisphosphonate use for more than 5 years is associated with 2.7-fold risk in subtrochanteric or shaft fractures; but the absolute risk is low at about 1 fracture per 1000 bisphosphonate users yearly. In one study, atypical femoral fractures developed in 4 of 327 patients after receiving at least 24 intravenous bisphosphonate infusions for bone metastases. Atypical fractures are subtrochanteric or diaphyseal, occur with little trauma, and are usually transverse as opposed to the more typical comminuted or spiral femoral shaft fractures. Bilateral femoral fractures occur in 27%. About 70% of affected patients have had prodromal thigh pain prior to the fracture. The risk for atypical femoral fractures is particularly increased among patients concurrently taking high-dose corticosteroids and those receiving treatment for more than 5 years. Teriparatide may be helpful to promote healing of such fractures. Despite this rare complication, the overall risk of hip fracture is reduced among patients taking bisphosphonates for up to 5 years.

Patients taking oral bisphosphonates have an increased risk of developing esophageal cancer. In North America and Europe, the incidence of esophageal cancer at age 60–79 is about 1 per 1000 population over 5 years; this risk is estimated to increase to about 2 per 1000 with administration of oral bisphosphonates for 5 years or longer.

In patients taking bisphosphonates, hypercalcemia is seen in 20% and serum PTH levels increase above normal in 10%, mimicking primary hyperparathyroidism. Hypercalcemia occurs frequently, resulting in secondary hyperparathyroidism. The half-life of alendronate in bone is 10 years. Therefore, bisphosphonates may be discontinued after a 5-year course of therapy. Repeat bone densitometry may be obtained after 3 years of bisphosphonate therapy. Bone density falls in 18% of women during their first year of treatment with bisphosphonates, but 80% of such patients have gain in bone density with continued bisphosphonate treatment.

3. Sex hormones—Hypogonadal women who take estrogen replacement therapy (ERT) have a lower risk of developing osteoporosis. Postmenopausal estrogen replacement is valuable as an osteoporosis prevention measure and this should be one factor in the complex decision about whether to take ERT. Low doses of estrogen appear to be adequate to prevent postmenopausal osteoporosis (see Estrogen Replacement Therapy). Once osteoporosis has developed, estrogen replacement is not an effective treatment. Men with hypogonadism may be treated with testosterone (see Male Hypogonadism).

4. Selective estrogen receptor modulators—Raloxifene, 60 mg/d orally, can be used by postmenopausal women in place of estrogen for prevention of osteoporosis. Bone density increases about 1% over 2 years in postmenopausal women versus 2% increases with estrogen replacement. It reduces the risk of vertebral fractures by about 40% but does not appear to reduce the risk of nonvertebral fractures. Raloxifene produces a reduction in LDL cholesterol but not the rise in high-density lipoprotein (HDL) cholesterol seen with estrogen. It has no direct effect on coronary plaque. Unlike estrogen, raloxifene does not reduce hot flushes; in fact, it often intensifies them. It does not relieve vaginal dryness. Unlike estrogen, raloxifene does not cause endometrial hyperplasia, uterine bleeding, or cancer, nor does it cause breast soreness. The risk of breast cancer is reduced 76% in women taking raloxifene for 3 years. Since it is a potential teratogen, it is relatively contraindicated in women capable of pregnancy.

Raloxifene increases the risk for thromboembolism and should not be used by women with such a history. Leg cramps can also occur.

5. Teriparatide—Teriparatide (Forteo, Parathar) is an analog of PTH. Teriparatide stimulates the production of new collagenous bone matrix that must be mineralized. Patients receiving teriparatide must have sufficient intake of vitamin D and calcium. When administered to patients
osteomalacia. Bisphosphonates and raloxifene can reverse progressive osteopenia and osteoporosis and decrease fracture risk.

Hypogonadal men are also at risk for developing osteoporosis. Testosterone administration can prevent osteoporosis. Men with prostate cancer may not receive testosterone replacement and should be monitored with bone densitometry. Bisphosphonate therapy can reverse progressive osteopenia and osteoporosis in men.

OSTEOMALACIA

**ESSENTIALS OF DIAGNOSIS**

- Painful proximal muscle weakness (especially pelvic girdle); bone pain and tenderness.
- Decreased bone density from defective mineralization.
- Laboratory abnormalities may include increased alkaline phosphatase, decreased 25-hydroxyvitamin D, hypocalcaemia, hypocalsuria, hypophosphataemia, secondary hyperparathyroidism.
- Classic radiologic features may be present.

**General Considerations**

Defective mineralization of the growing skeleton in childhood causes permanent bone deformities (rickets). Defective skeletal mineralization in adults is known as osteomalacia. It is caused by any condition that results in
inadequate calcium or phosphate mineralization of bone osteoid.

**Etiology (Table 26–11)**

**A. Vitamin D Deficiency and Resistance**

Vitamin D is predominantly synthesized in the skin during exposure to ultraviolet B light. Vitamin D is also consumed in the diet from plants (ergocalciferol, D2) or animals/fish (cholecalciferol, D3). Both forms of vitamin D are converted in the liver to 25-hydroxyvitamin D (25OHD); 25OHD is subsequently converted in various tissues (mainly kidney) to 1,25-dihydroxyvitamin D (1,25(OH)2D), the active hormone whose production is regulated by serum calcium, phosphorus, and PTH. 1,25(OH)2D binds to cytoplasmic vitamin D receptors, increasing the absorption of dietary calcium from the intestine and increasing the reabsorption of calcium in the renal tubule, thereby reducing calcium loss in the urine. 1,25(OH)2D also stimulates bone osteoblasts to release RANKL that stimulates osteoclasts, which release calcium from bone.

Unexpectedly, vitamin D receptors have been found in most tissues in the body (eg, brain, heart, breast, prostate) that have nothing to do with calcium homeostasis. The function of these vitamin D receptors is unknown. Much of the recent interest in vitamin D has been sparked by epidemiology studies relating an increased prevalence of cancer, diabetes mellitus, cardiovascular disease, and multiple sclerosis to lower serum levels of 25OHD. Such association studies suffer from the fact that healthy individuals have more sun exposure and a better diet, such that low serum 25OHD levels may be the result of the disease rather than the cause of it.

Vitamin D deficiency is the most common cause of osteomalacia and its incidence is increasing throughout the world as a result of diminished exposure to sunlight caused by urbanization, automobile and public transportation, modest clothing, and sunscreen use. Significant vitamin D deficiency (serum 25OHD < 50 nmol/L or < 20 ng/mL) was found in 24.3% of postmenopausal women from 25 countries in the Multiple Outcomes of Raloxifene Evaluation (MORE) study. The incidence varied: < 1% in Southeast Asia, 29% in the United States, and 36% in Italy. Severe vitamin D deficiency (serum 25OHD < 25 nmol/L or < 10 ng/mL) was found in 4% of these women; 3.5% in the United States and 12.5% in Italy. Among US men over age 65 years, 25% have serum 25OHD levels below 20 ng/mL; men over age 75 with such low vitamin D levels have particularly accelerated bone loss. Vitamin D deficiency is particularly common in the institutionalized elderly, with the incidence exceeding 60% in some groups not receiving vitamin D supplementation. Deficiency of vitamin D may arise from insufficient sun exposure, malnutrition, or malabsorption (due to pancreatic insufficiency, cholestatic liver disease, sprue, inflammatory bowel disease, jejunoileal bypass, Billroth type II gastrectomy). Orlistat is a weight-loss medication that causes fat malabsorption and reduced serum 25OHD levels. Cholestyramine binds bile acids necessary for vitamin D absorption. Patients with severe nephrotic syndrome lose large amounts of vitamin D–binding protein in the urine, and osteomalacia may also develop.

Anticonvulsants (eg, phenytoin, carbamazepine, valproate, phenobarbital) inhibit the hepatic production of 25OHD and sometimes cause osteomalacia. Phenytoin can also directly inhibit bone mineralization. Serum levels of 1,25(OH)2D are usually normal.

Vitamin D–dependent rickets type I is caused by a rare autosomal recessive disorder with a defect in the renal enzyme 1-α-hydroxylase leading to defective synthesis of 1,25(OH)2D. It presents in childhood with rickets and alopecia; osteomalacia develops in adults with this condition unless treated with oral calcitriol in doses of 0.5–1 mcg daily.

Vitamin D–dependent rickets type II (better known as hereditary 1,25(OH)2D-resistant rickets) is caused by a genetic defect in the 1,25(OH)2D receptor. Patients have hypocalcaemia with childhood rickets and adult osteomalacia. Alopecia is common. These patients respond variably to oral calcitriol in very large doses (2–6 mcg daily).

**B. Deficient Calcium Intake**

Rickets and osteomalacia continue to be common problems in many tropical countries despite adequate exposure to sunlight. A nutritional deficiency of calcium can occur in any severely malnourished patient. Some degree of calcium deficiency is common in the elderly, since intestinal

*See Table 26–10 for causes of osteoporosis.*
calcium absorption declines with age. Ingestion of excessive wheat bran also causes calcium malabsorption.

C. Phosphate Deficiency

Clinical symptoms of phosphate deficiency include severe muscle weakness and bone pain. Phosphate deficiency in childhood causes classic rickets, whereas phosphate deficiency in adulthood causes osteomalacia. 1. Genetic disorders—Fibroblast growth factor-23 (FGF23) is a phosphaturic factor (phosphatonin) that is secreted by bone osteoblasts in response to elevated serum phosphate levels. Families with autosomal dominant hypophosphatemic rickets have a gain-of-function mutation in the gene encoding FGF23 that makes it resistant to proteolytic cleavage, thereby increasing serum FGF23 levels. In X-linked hypophosphatemic rickets, there is a mutation in the gene encoding PHEX endopeptidase, which fails to cleave FGF23, resulting in elevated serum FGF23 levels. An autosomal recessive form of hypophosphatemic rickets is caused by mutations in DMP1, a transcription factor that regulates FGF23 production in bone. All three conditions have high serum FGF23 levels causing hypophosphatemia and bone mineral depletion.

Sodium-phosphate cotransporters (NPT2a or NPT2c) reabsorb phosphate from the proximal renal tubule. Mutations in the genes encoding them or in NHERF1 cause hypophosphatemia, bone mineral depletion, and calcium-phosphate kidney stones.

2. Tumor-induced osteomalacia—A variety of mesenchymal tumors (87% benign) secrete fibroblast growth factor-23 (FGF23, see above) and cause marked hypophosphatemia due to renal phosphate wasting. Such tumors are usually small and are often difficult to locate. The condition is characterized by hypophosphatemia, excessive phosphaturia, reduced or normal serum 1,25(OH)₂D concentrations, and osteomalacia. Serum levels of FGF23 are elevated. Such tumors are often small and difficult to find, frequently lying in extremities. Imaging with ¹¹¹In-octreotide or ¹⁸FDG-PET should include the entire body and may be helpful in localizing these tumors.

3. Other causes of hypophosphatemia—Osteomalacia from hypophosphatemia can be caused by poor nutrition, and severe hypophosphatemia can occur with refeeding after starvation. Other causes of hypophosphatemic osteomalacia include alcoholism and chelation of phosphate in the gut by aluminum hydroxide antacids, calcium acetate (Phos-Lo), or sevelamer hydrochloride (Renagel). Excessive renal phosphate losses are also seen in proximal renal tubular acidosis and Fanconi syndrome.

D. Aluminum Toxicity

Bone mineralization is inhibited by aluminum. Osteomalacia may occur in patients receiving long-term renal hemodialysis with tap water dialyseate or from aluminum-containing antacids used to reduce phosphate levels. Osteomalacia may develop in patients being maintained on long-term total parenteral nutrition if the casein hydrolysate used for amino acids contains high levels of aluminum.

E. Hypophosphatasia

Hypophosphatasia, a deficiency of bone alkaline phosphatase effect, is a rare genetic cause of osteomalacia that is commonly misdiagnosed as osteoporosis. The incidence in the United States is about 1 in 100,000 live births; about 1 in 300 adults is a carrier. Many different mutations in the gene (designated ALPL) encoding bone alkaline phosphatase have been described, and transmission can be either autosomal recessive or autosomal dominant. The phenotypic presentation of hypophosphatasia is extremely variable. At its worst extreme, it can present as a stillborn without dentition or calcified bones. At its mildest, hypophosphatasia can present in middle age with premature loss of teeth, foot pain (due to metatarsal stress fractures), thigh pain (due to femoral pseudofractures), or arthritis (due to chondrocalcinosis). Serum alkaline phosphatase (collected in a non-EDTA tube) is low for age in patients with hypophosphatasia. To confirm the diagnosis, a 24-hour urine should be assayed for phosphoethanolamine, a substrate for tissue-nonspecific alkaline phosphatase, whose excretion is always elevated in patients with hypophosphatasia. Prenatal genetic testing, by way of chorionic villus biopsy, is available for the infantile form of hypophosphatasia. There is no proven therapy for hypophosphatasia, except for supportive care. Teriparatide, a useful therapy for osteoporosis, has been administered to some patients with hypophosphatasia, but its long-term efficacy is unknown.

F. Fibrogenesis Imperfecta Ossium

This rare condition sporadically affects middle-aged patients, who present with progressive bone pain and pathologic fractures. Bones have a dense “fishnet” appearance on radiographs. Serum alkaline phosphatase levels are elevated. Some patients have a monoclonal gammopathy, indicating a possible plasma cell dyscrasia causing an impairment in osteoblast function and collagen disarray. Remission has been reported after repeated courses of melphalan, corticosteroids, and vitamin D analog over 3 years.

Clinical Findings

The clinical manifestations of defective bone mineralization depend on the age at onset and the severity. In infants and children, vitamin D deficiency can cause severe hypocalcemia with muscle weakness; heart failure; laryngospasm; and rickets with bone pain, fractures, bone deformities, and dental problems. In adults, osteomalacia is typically asymptomatic at first. Eventually, bone pain occurs, along with muscle weakness due to calcium deficiency. Pathologic fractures may occur with little or no trauma. Vitamin D deficiency has also been associated with a possible increased risk of multiple sclerosis, rheumatoid arthritis, diabetes mellitus (types 1 and 2), and other conditions, but the causal relationship is uncertain.

Diagnostic Tests

Serum is obtained for calcium, albumin, phosphate, alkaline phosphatase, PTH, and 25[OH]D₃ determinations. Bone densitometry helps document the degree of osteopenia. Radiographs may show diagnostic features.
In one series of biopsy-proved osteomalacia, alkaline phosphatase was elevated in 94% of patients; the calcium or phosphorus was low in 47% of patients; 25(OH)D$_3$ was low in 29% of patients; pseudofractures were seen in 18% of patients; and urinary calcium was low in 18% of patients. 1,25(OH)$_2$D$_3$ may be low even when 25(OH)D$_3$ levels are normal.

Bone biopsy is not usually necessary but is diagnostic of osteomalacia if there is significant unmineralized osteoid.

### Differential Diagnosis

Osteomalacia is often seen together with osteoporosis, and its presence can be inferred by finding low serum levels of 25(OH) vitamin D, low serum calcium, or low serum phosphate. A high serum alkaline phosphatase may be present in severe osteomalacia but not osteoporosis. The relative contribution of the two entities to diminished bone density may not be apparent until treatment, since a dramatic rise in bone density is often seen with therapy for osteomalacia. Phosphate deficiency must be distinguished from hypophosphatemia seen in hyperparathyroidism.

### Prevention & Treatment

To obtain adequate sunshine vitamin D, the face, arms, hands, or back must have sun exposure without sunscreen for 15 minutes at least twice weekly. The main natural food source of vitamin D is fish, particularly salmon, mackerel, cod liver oil, and sardines or tuna canned in oil. Most commercial cow’s milk is fortified with vitamin D at about 400 international units per quart; however, skim milk and other dairy products contain much less vitamin D.

Many vitamin supplements contain plant-derived vitamin D$_2$, which has less biologic availability than once believed. Over-the-counter multivitamin/mineral supplements contain variable amounts of vitamin D, and vitamin D toxicity has occurred from two different multivitamins sold in the United States. Therefore, it is prudent to recommend that patients take a dedicated vitamin D supplement from a reliable manufacturer.

In sunlight-deprived individuals (eg, veiled women, confined patients, or residents of higher latitudes during winter), the recommended daily allowance should be vitamin D$_3$ 1000 international units daily. In such individuals, vitamin D$_3$ supplements should be given prophylactically. Patients receiving long-term phenytoin therapy may be treated prophylactically with vitamin D, 50,000 international units orally every 2–4 weeks.

Frank vitamin D deficiency is treated with ergocalciferol (D$_2$), 50,000 international units orally once weekly for 8 weeks. Following that, vitamin D$_3$ (cholecalciferol) supplementation is used at a dose of 2000 international units daily. Vitamin D$_3$ is more effective than vitamin D$_2$ in raising serum levels of 25(OH)D. Some patients require long-term supplementation with ergocalciferol of up to 50,000 international units weekly. In patients with intestinal malabsorption, oral doses of 25,000–100,000 international units of vitamin D$_3$ daily may be required. Some patients with steatorrhea respond better to oral 25(OH)D$_3$ (calcifediol), 50–100 mcg/d. Serum levels of 25(OH)D should be monitored and the dosage of vitamin D adjusted to maintain serum 25(OH)D levels above 30 ng/mL. During treatment with high-dose vitamin D, serum calcium should also be monitored to avoid hypercalcemia.

Beyond increasing the intestinal absorption of calcium, vitamin D supplementation may have additional effects. Vitamin D supplementation has been associated with improved muscle strength and a reduced fall risk, factors that reduce the risk of bone fracture.

The addition of calcium supplements to vitamin D is probably not necessary for the prevention of osteomalacia in the majority of otherwise well-nourished patients. However, patients with malabsorption or poor nutrition should receive calcium supplementation. Recommended doses of calcium are as follows: calcium citrate (eg, Citracal), 0.4–0.6 g elemental calcium per day, or calcium carbonate (eg, OsCal, Tums), 1–1.5 g elemental calcium per day. Calcium supplements are best administered with meals.

In hypophosphatemic osteomalacia, nutritional deficiencies are corrected, aluminum-containing antacids are discontinued, and patients with renal tubular acidosis are given bicarbonate therapy. In patients with sporadic adult-onset hypophosphatemia, hyperphosphaturia, and low serum 1,25(OH)$_2$D$_3$ levels, a search is conducted for occult tumors that may be resected; whole-body MRI scanning may be required.

For those with X-linked or idiopathic hypophosphatemia and hyperphosphaturia, oral phosphate supplements must be given long-term; calcitriol, 0.25–0.5 mcg/d, is given also to improve the impaired calcium absorption caused by the oral phosphate. If necessary, rhGH may be added to the above regimen to reduce phosphaturia.

Patients with hypophosphatasia have been treated with teriparatide with improvement in bone pain and fracture healing.
Paget disease of bone is a common condition manifested by one or more bony lesions having high bone turnover and disorganized osteoid formation. Involved bones become vascular, weak, and deformed. Paget disease is most common in the United Kingdom but is also common in other areas of the world, particularly in those with British ancestry. It is uncommon in Africa, Asia, and Scandinavia. Paget disease is present in 1–2% of the population of the United States and affects men more commonly than women. It is usually diagnosed in patients over age 40 years and its prevalence doubles with each decade thereafter, reaching an incidence of about 10% after age 80. It is usually discovered incidentally during radiology imaging or because of incidentally discovered elevations in serum alkaline phosphatase. The cause of Paget disease is unknown. However, there is often a genetic component since about 15% of affected patients have a first-degree relative with the disease. Similar familial disorders occur at an earlier age and their genetics has been established.

### General Considerations

Paget disease of bone is often mild and asymptomatic. Only 27% of affected individuals are symptomatic at the time of diagnosis. It can involve just one bone (monostotic) or multiple bones (polyostotic), particularly the skull, femur, tibia, pelvis, and humerus. The affected bones are typically involved right away and the disease tends not to involve additional bones during its course. Pain is the usual first symptom. It may occur in the involved bone or in an adjacent joint, which can be involved with degenerative arthritis. The bones can become soft, leading to bowed tibias, kyphosis, and frequent “chalkstick” fractures with slight trauma. If the skull is involved, the patient may report headaches and an increased hat size. Deafness may occur. Increased vascularity over the involved bones causes increased warmth and can cause vascular “steal” syndromes.

### Clinical Findings

#### A. Symptoms and Signs

Paget disease is often mild and asymptomatic. Only 27% of affected individuals are symptomatic at the time of diagnosis. It can involve just one bone (monostotic) or multiple bones (polyostotic), particularly the skull, femur, tibia, pelvis, and humerus. The affected bones are typically involved right away and the disease tends not to involve additional bones during its course. Pain is the usual first symptom. It may occur in the involved bone or in an adjacent joint, which can be involved with degenerative arthritis. The bones can become soft, leading to bowed tibias, kyphosis, and frequent “chalkstick” fractures with slight trauma. If the skull is involved, the patient may report headaches and an increased hat size. Deafness may occur. Increased vascularity over the involved bones causes increased warmth and can cause vascular “steal” syndromes.

#### B. Laboratory Findings

Serum alkaline phosphatase is usually markedly elevated. However, some patients with limited monostotic involvement may have serum alkaline phosphatase levels within the normal range. A serum bone-specific alkaline phosphatase determination can be useful for patients with a normal serum total alkaline phosphatase level and to distinguish the source of an elevated serum alkaline phosphatase as being from bone (rather than liver). Other markers of bone turnover may be elevated. Serum C-telopeptide (CTx) is usually high. Urinary hydroxyproline is also elevated in active disease. Serum calcium may be elevated, particularly if the patient is at bed rest. A serum 25-OH vitamin D determination should be obtained to screen for vitamin D deficiency, which can also present with an increased alkaline phosphatase and bone pain. Also, any vitamin D deficiency should be corrected before prescribing a bisphosphonate.

### C. Imaging

On radiographs, the initial lesions are typically osteolytic, with focal radiolucencies (“osteoporosis circumscripta”) in the skull or advancing flame-shaped lytic lesions in long bones. Bone lesions may subsequently become sclerotic and have a mixed lytic and sclerotic appearance. The affected bones eventually become thickened and deformed. Technetium pyrophosphate bone scans are helpful in delineating activity of bone lesions even before any radiologic changes are apparent.

### Differential Diagnosis

Certain rare familial osteoclastic bone disorders share phenotypic homologies with Paget disease of bone. Familial expansile osteolysis, familial early-onset Paget disease, and familial skeletal hyperphosphatasia are autosomal dominant disorders caused by different tandem duplications of the gene encoding RANK, resulting in its constitutive activation. Juvenile Paget disease is an autosomal recessive disorder caused by an inactivating mutation in the gene encoding osteoprotegerin. The syndrome of Paget disease, inclusion body myopathy, and frontotemporal dementia is caused by a mutation in the gene that encodes valosin-containing protein.

Paget disease must be differentiated from primary bone lesions such as osteogenic sarcoma, multiple myeloma, and fibrous dysplasia and from secondary bone lesions such as metastatic carcinoma and osteitis fibrosa cystica. Fibrogenesis imperfecta ossium is a rare symmetric disorder that can mimic the features of Paget disease; alkaline phosphatase is likewise elevated. If serum calcium is elevated, hyperparathyroidism may be present in some patients as well.

### Complications

If immobilization occurs, hypercalcemia and renal calculi may develop. Vertebral collapse may lead to spinal cord compression. The increased vascularity may give rise to high-output cardiac failure. Arthritis frequently develops in joints adjacent to involved bone.

Extensive skull involvement may cause cranial nerve palsies from impingement of the neural foramina. Involvement of the petrous temporal bone frequently causes hearing loss (mixed sensorineural and conductive)
and occasionally tinnitus or vertigo. Vertebral involvement can cause compression of spinal nerves, resulting in radiculopathy or paralysis. The affected bones have a high blood flow and can thereby cause a vascular “steal” syndrome. Skull involvement can cause a vascular steal syndrome with somnolence or ischemic neurologic events; the optic nerve may be affected, resulting in loss of vision. Vertebral involvement can cause a vascular steal syndrome with paralysis. Jaw involvement can cause the teeth to spread intraorally and become misaligned.

Osteosarcoma may develop in long-standing lesions but is rare (<1%). Sarcomatous change is suggested by a marked increase in bone pain, sudden rise in alkaline phosphatase, and appearance of a new lytic lesion.

**Treatment**

Asymptomatic patients may require only clinical surveillance and no treatment. However, treatment should be considered for asymptomatic patients who have extensive involvement of the skull, long bones, or vertebrae. Patients must be monitored carefully before, during, and after treatment with clinical examinations and serial serum alkaline phosphatase determinations.

**A. Bisphosphonates**

Bisphosphonates are the treatment of choice for Paget disease. Bisphosphonates are usually given cyclically. Therapy is given until a therapeutic response occurs, as evidenced by normalization of the serum alkaline phosphatase. After a course of therapy, patients are given a break for about 3 months or until the serum alkaline phosphatase begins rising again; another cycle is then commenced.

Patients frequently experience a paradoxical increase in pain soon after commencing bisphosphonate therapy; this is the “first dose effect” and the pain usually subsides with further treatment. Flu-like symptoms occur fairly frequently. Osteonecrosis, particularly of the jaw, is rare but can occur spontaneously or after tooth extraction.

The oral bisphosphonates should all be taken with 8 oz of plain water only; they are relatively contraindicated in patients with a history of esophagitis, esophageal stricture, dysphagia, hiatal hernia, or achalasia. **Alendronate**, 40 mg orally daily for 3–6 month cycles, must be taken in the morning with water only, at least 30–40 minutes before any other food, liquids, or medications. Patients should not lie down for at least 30 minutes after taking alendronate to reduce the risk of esophagitis.

Parenteral bisphosphonates are particularly useful for patients who cannot tolerate oral bisphosphonates. Intravenous bisphosphonates can produce clinical improvements that last several months. Serum alkaline phosphatase levels may continue to drop for 6 months after treatment. They appear to be more effective than oral bisphosphonates but have more systemic side effects. Postinfusion fever, fatigue, myalgia, bone pain, and ocular problems occur commonly and may sometimes be severe. Serious side effects are rare but include uveitis and acute kidney disease. Hypocalcemia is common and may be severe, especially if intravenous bisphosphonates are given along with loop diuretics. It is advisable to administer calcium and vitamin D supplements, especially during the first 2 weeks following treatment. Asthma may occur in aspirin-sensitive patients. **Pamidronate**, 30–60 mg is infused intravenously over 2–4 hours. Depending on the disease severity, one to three additional doses may be given days or weeks apart. **Zoledronic acid** can be given every 6–12 months in doses of 2–5 mg intravenously over 20 minutes. Six months following a single infusion of zoledronic acid, patients had a clinical response rate of 96%, compared with 74% in patients receiving daily oral risedronate. Intravenous zoledronic acid has been demonstrated to be significantly more effective than daily risedronate. Bisphosphonates have significant side effects (see Osteoporosis, above).

**B. Nasal Calcitonin-Salmon**

Calcitonin-salmon, 200 international units/unit dose spray, is administered as one spray daily, alternating nostrils. It is just as effective as the parenteral preparation and is associated with fewer side effects. Nasal irritation may occur, as may occasional epistaxis. However, the use of calcitonin has declined dramatically with the introduction of more potent bisphosphonates.

**Prognosis**

The prognosis in general is good, but sarcomatous changes (in 1–3%) can alter it unfavorably. In general, the prognosis is worse the earlier in life the disease starts. Fractures usually heal well. In the severe forms, marked deformity, intractable pain, and cardiac failure are found. These complications should become rare with prompt bisphosphonate treatment.

DISEASES OF THE ADRENAL CORTEX

ACUTE ADRENOCORTICAL INSUFFICIENCY (Adrenal Crisis)

**Essentials of Diagnosis**

- Weakness, abdominal pain, fever, confusion, nausea, vomiting, and diarrhea.
- Low blood pressure, dehydration; skin pigmentation may be increased.
- Serum potassium high, sodium low, BUN high.
- Cosyntropin (ACTH1–24) unable to stimulate an increase in serum cortisol to \( \geq 20 \text{ mcg/dL} \).

**General Considerations**

Acute adrenal insufficiency is an emergency caused by insufficient cortisol. Crisis may occur in the course of treatment of chronic insufficiency, or it may be the presenting manifestation of adrenal insufficiency. Acute adrenal crisis is more commonly seen in primary adrenal insufficiency (Addison disease) than in disorders of the pituitary gland causing secondary adrenocortical hypofunction.

Adrenal crisis may occur in the following situations:
1. During stress, (eg, trauma, surgery, infection, hyperthyroidism, or prolonged fasting) in a patient with latent or temporary insufficiency or in a patient with temporary insufficiency due to suppression by exogenous corticosteroids or megestrol; (3) following bilateral adrenalectomy or removal of a functioning adrenal tumor that had suppressed the other adrenal; (4) following sudden destruction of the pituitary gland (pituitary necrosis), or when thyroid hormone is given to a patient with hypoadrenalism; and (5) following administration of etomidate.
2. Following sudden withdrawal of adrenocortical hormone in a patient with chronic insufficiency or in a patient with temporary insufficiency due to suppression by exogenous corticosteroids or megestrol.
3. Following bilateral adrenalectomy or removal of a functioning adrenal tumor that had suppressed the other adrenal.
4. Following sudden destruction of the pituitary gland (pituitary necrosis), or when thyroid hormone is given to a patient with hypoadrenalism; and (5) following injury to both adrenals by trauma, hemorrhage, anticoagulant therapy, thrombosis, infection or, rarely, metastatic carcinoma; (6) following administration of etomidate, which is used intravenously for rapid anesthesia induction or intubation.

**Clinical Findings**

**A. Symptoms and Signs**

The patient complains of headache, lassitude, nausea and vomiting, abdominal pain, and often diarrhea. Confusion or coma may be present. Fever may be 40.6 °C or more. The blood pressure is low. Recurrent hypoglycemia and reduced insulin requirements may present in patients with preexisting type 1 diabetes mellitus. Other signs may include cyanosis, dehydration, skin hyperpigmentation, and sparse axillary hair (if hypogonadism is also present). Meningococcemia may be associated with purpura and adrenal insufficiency secondary to adrenal infarction (Waterhouse–Friderichsen syndrome).

**B. Laboratory Findings**

The eosinophil count may be high. Hyponatremia or hyperkalemia (or both) are usually present. Hypoglycemia is frequent. Hypercalcemia may be present. Blood, sputum, or urine culture may be positive if bacterial infection is the precipitating cause of the crisis.

The diagnosis is made by a simplified cosyntropin stimulation test, which is performed as follows: (1) Synthetic ACTH1–24 (cosyntropin), 0.25 mg, is given intramuscularly. (2) Serum is obtained for cortisol between 30 and 60 minutes after cosyntropin is administered. Normally, serum cortisol rises to at least 20 mcg/dL. For patients receiving corticosteroid treatment, hydrocortisone must not be given for at least 8 hours before the test. Other corticosteroids (eg, prednisone, dexamethasone) do not interfere with specific assays for cortisol.

Plasma ACTH is markedly elevated if the patient has primary adrenal disease (generally \( \geq 200 \text{ pg/mL} \)).

**Differential Diagnosis**

Acute adrenal insufficiency must be distinguished from other causes of shock (eg, septic, hemorrhagic, cardiogenic). Hyperkalemia is also seen with gastrointestinal bleeding, rhabdomyolysis, hyperkalemic paralysis, and certain drugs (eg, angiotensin-converting enzyme [ACE] inhibitors, spironolactone). Hyponatremia is seen in many other conditions (eg, hypothyroidism, diuretic use, heart failure, cirrhosis, vomiting, diarrhea, severe illness, or major surgery). Acute adrenal insufficiency must be distinguished from an acute abdomen in which neutrophilia is the rule, whereas adrenal insufficiency is characterized by a relative lymphocytosis and eosinophilia.

More than 90% of serum cortisol is protein bound and low serum levels of binding proteins result in misleadingly low serum cortisol determinations by most assays. Nearly 40% of critically ill patients, with serum albumin <2.5 g/dL, have low serum total cortisol levels but normal serum free cortisol or salivary cortisol levels and normal adrenal function.

**Treatment**

**A. Acute Phase**

If the diagnosis is suspected, draw a blood sample for cortisol determination and treat with hydrocortisone, 100–300 mg intravenously, and saline immediately, without waiting for the results. Thereafter, give hydrocortisone phosphate or hydrocortisone sodium succinate, 100 mg intravenously immediately, and continue intravenous infusions of 50–100 mg every 6 hours for the first day. Give the same amount every 8 hours on the second day and then adjust the dosage in view of the clinical picture.

Since bacterial infection frequently precipitates acute adrenal crisis, broad-spectrum antibiotics should be administered empirically while waiting for the results of initial cultures. Hypoglycemia should be vigorously treated while serum electrolytes, BUN, and creatinine are monitored.

**B. Convalescent Phase**

When the patient is able to take food by mouth, give oral hydrocortisone, 10–20 mg every 6 hours, and reduce dosage
to maintenance levels as needed. Most patients ultimately require hydrocortisone twice daily (AM, 10–20 mg; PM, 5–10 mg). Mineralocorticoid therapy is not needed when large amounts of hydrocortisone are being given, but as the dose is reduced it is usually necessary to add fludrocortisone acetate, 0.05–0.2 mg orally daily. Some patients never require fludrocortisone or become edematous at doses of more than 0.05 mg once or twice weekly. Once the crisis has passed, the patient must be evaluated to assess the degree of permanent adrenal insufficiency and to establish the cause if possible.

- **Prognosis**
  Rapid treatment will usually be lifesaving. However, acute adrenal insufficiency is frequently unrecognized and untreated since its manifestations mimic more common conditions; lack of treatment leads to shock that is unresponsive to volume replacement and vasopressors, resulting in death.

### CHRONIC ADRENOCORTICAL INSUFFICIENCY (Addison Disease)

- **Essentials of Diagnosis**
  - Weakness, fatigability, anorexia, weight loss; nausea and vomiting, diarrhea; abdominal pain, muscle and joint pains; amenorrhea.
  - Sparse axillary hair; increased skin pigmentation, especially of creases, pressure areas, and nipples.
  - Hypotension, small heart.
  - Serum sodium may be low; potassium, calcium, and BUN may be elevated; neutropenia, mild anemia, eosinophilia, and relative lymphocytosis may be present.
  - Plasma cortisol levels are low or fail to rise after administration of corticotropin.
  - Plasma ACTH level is elevated.

- **General Considerations**
  Addison disease refers to primary adrenal insufficiency caused by dysfunction or absence of the adrenal cortices. It is distinct from secondary adrenal insufficiency caused by deficient secretion of ACTH. (See Anterior Hypopituitarism.)

Addison disease is an uncommon disorder with a prevalence of about 140 per million and an annual incidence of about 4 per million in the United States. Addison disease is characterized by chronic deficiency of cortisol, with consequent elevation of serum ACTH causing skin pigmentation that can be subtle or strikingly dark. Patients with destruction of the adrenal cortices or with classic 21-hydroxylase deficiency also have mineralocorticoid deficiency with hyponatremia, volume depletion, and hyperkalemia. In contrast, mineralocorticoid deficiency is not present in patients with familial glucocorticoid deficiency and Allgrove syndrome (see below).

- **Etiology**
  Autoimmune destruction of the adrenals is the most common cause of Addison disease in the United States (accounting for about 80% of spontaneous cases). With such autoimmunity, adrenal function decreases over several years as it progresses to overt adrenal insufficiency. It may occur alone or as part of a polyglandular autoimmune (PGA) syndrome. Type 1 PGA is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome and is caused by a defect in T cell-mediated immunity inherited as an autosomal recessive trait. Type 1 PGA usually presents in early childhood with mucocutaneous candidiasis, followed by hypoparathyroidism and dystrophy of the teeth and nails; Addison disease usually appears by age 15 years. Partial or late expression of the syndrome is common. A varied spectrum of associated diseases may be seen in adulthood, including hypogonadism, hypothyroidism, pernicious anemia, alopecia, vitiligo, hepatitis, malabsorption, and Sjögren syndrome.

  Type 2 PGA usually presents in young adults age 20–40 years, usually women (female: male ratio is 3:1). The following conditions may be presentations of type 2 PGA: autoimmune adrenal insufficiency, type 1 diabetes mellitus, or autoimmune thyroid disease (usually hypothyroidism, sometimes hyperthyroidism). The combination of Addison disease and hypothyroidism is known as Schmidt syndrome. Patients may also have vitiligo, alopecia areata, Sjögren syndrome, or celiac sprue. Type 2 PGA is also associated with autoimmune primary ovarian failure; testicular failure (5%); pernicious anemia (4%); and, rarely, autoimmune hypophysitis, encephalitis, or hypoparathyroidism (late-onset).

  **Tuberculosis** as a leading cause of Addison disease is relatively rare in the United States but common where tuberculosis is more prevalent.

  Bilateral adrenal hemorrhage may occur during sepsis, heparin-associated thrombocytopenia or anticoagulation, or with antiphospholipid antibody syndrome. It may occur in association with major surgery or trauma, presenting about 1 week later with pain, fever, and shock. It may also occur spontaneously and present with flank pain; MRI may show adrenal enlargement with increased T2-weighted imaging.

  **Adrenoleukodystrophy** is an X-linked peroxisomal disorder causing accumulation of very long-chain fatty acids in the adrenal cortex, testes, brain, and spinal cord. It may present at any age and accounts for one-third of cases of Addison disease in boys. Aldosterone deficiency occurs in 9%. Hypogonadism is common. Psychiatric symptoms
often include mania, psychosis, or cognitive impairment. Neurologic deterioration may be severe or mild (particularly in heterozygote women), mimics symptoms of multiple sclerosis, and can occur years after the onset of adrenal insufficiency.

Rare causes of adrenal insufficiency include lymphoma, metastatic carcinoma, coccidiodomycosis, histoplasmosis, cytomegalovirus infection (more frequent in patients with AIDS), syphilitic gummata, scleroderma, amyloid disease, and hemochromatosis.

Congenital adrenal insufficiency occurs in several conditions. Familial glucocorticoid deficiency is an autosomal recessive disease that is caused by mutations in the adrenal ACTH receptor (melanocortin 2 receptor, MC2R). It is a recessive disease that is caused by mutations in the adrenal glucocorticoid receptor (NR3C1) gene. This results in adrenal insufficiency, achalasia, alacrima, nasal voice, autonomic dysfunction, and neuroendocrine disease.

Triple A (Allgrove) syndrome is caused by a mutation in the AAAS gene that encodes a protein known as ALADIN (alacrima, achalasia, adrenal insufficiency, neurologic disorder). It is characterized by variable expression of the following: adrenal ACTH resistance with cortisol deficiency, alacrima, alacrism, nasal voice, autonomic dysfunction, and neuromuscular disease of varying severity (hyperreflexia to spastic paraplegia). Cortisol deficiency usually presents in infancy but may not occur until the third decade of life.

Congenital adrenal hypoplasia causes adrenal insufficiency due to absence of the adrenal cortex; patients may also have hypogonadotropic hypogonadism, myopathy, and high-frequency hearing loss.

Patients with hereditary defects in adrenal enzymes for cortisol synthesis develop congenital adrenal hyperplasia due to ACTH stimulation. The most common enzyme defect is P450c21 (21-hydroxylase). Patients with severely defective P450c21 enzymes manifest deficiency of mineralocorticoids (salt wasting) in addition to deficient cortisol and excessive androgens. Women with milder enzyme defects may develop hirsutism in adolescence or adulthood and are said to have "late-onset" congenital adrenal hyperplasia. (See Hirsutism section.) Patients with deficient P450c17 (17 hydroxylase) have varying degrees of adrenocortical deficiency with associated hypertension, hypokalemia, and primary hypogonadism.

Drugs that cause primary adrenal insufficiency include mitotane and abiraterone acetate (Zytiga), which inhibits P450c17 for the treatment of men with prostate cancer but causes adrenocortical deficiency with hypertension and hyperkalemia.

### Clinical Findings

#### A. Symptoms and Signs

The symptoms may include weakness and fatigability, weight loss, myalgias, arthralgias, fever, anorexia, nausea and vomiting, anxiety, and mental irritability. Some of these symptoms may be due to high serum levels of IL-6. Pigmentary changes consist of diffuse tanning over nonexposed as well as exposed parts or multiple freckles; hyperpigmentation is especially prominent over the knuckles, elbows, knees, and posterior neck and in palmar creases. Nail beds may develop longitudinal pigmented bands. Nipples and areolas tend to darken. The skin in pressure areas such as the belt or brassiere lines and the buttocks also darkens. New scars are pigmented. Some patients have associated vitiligo (10%). Emotional changes are common. Hypoglycemia, when present, may worsen the patient’s weakness and mental functioning, rarely leading to coma. Manifestations of other autoimmune disease (see above) may be present. Patients tend to be hypotensive and orthostatic; about 90% have systolic blood pressures under 110 mm Hg; blood pressure over 130 mm Hg is rare. Other findings may include a small heart, hyperplasia of lymphoid tissues, and scant axillary and pubic hair (especially in women).

Patients with adult-onset adrenoleukodystrophy may present with neuropsychiatric symptoms, sometimes without adrenal insufficiency.

#### B. Laboratory Findings

The WBC count usually shows moderate neutropenia, lymphocytosis, and a total eosinophil count over 300/mcL. Among patients with chronic Addison disease, the serum sodium is usually low (90%) while the potassium is elevated (65%). Patients with diarrhea may not be hyperkalemic. Fasting blood glucose may be low. Hypercalcemia may be present. Young men with idiopathic Addison disease are screened for adrenoleukodystrophy by determining plasma very long-chain fatty acid levels; affected patients have high levels.

Low plasma cortisol (< 3 mcg/dL) at 8 AM is diagnostic, especially if accompanied by simultaneous elevation of the plasma ACTH level (usually > 200 pg/mL). The diagnosis is made by a simplified cosyntropin stimulation test, which is performed as follows: (1) Synthetic ACTH1–24 (cosyntropin), 0.25 mg, is given intramuscularly. (2) Serum is obtained for cortisol 45 minutes after cosyntropin is administered. Normally, serum cortisol rises to at least 20 mcg/dL. For patients receiving corticosteroid treatment, hydrocortisone must not be given for at least 8 hours before the test. Other corticosteroids (eg, prednisone, dexamethasone) do not interfere with specific assays for cortisol.

Serum DHEA levels are under 1000 ng/mL in 100% of patients with Addison disease and a serum DHEA above 1000 ng/mL excludes the diagnosis. However, serum DHEA levels below 1000 ng/mL are not helpful, since about 15% of the general population have such low DHEA levels, particularly children and elderly individuals. Antiadrenal antibodies are found in the serum in about 50% of cases of autoimmune Addison disease. Antibodies to thyroid (45%) and other tissues may be present.

Salt-wasting congenital adrenal hyperplasia due to 21-hydroxylase deficiency is usually diagnosed at birth in females due to ambiguous genitalia. Males and patients with milder enzyme defects may present later. The diagnosis of adrenal insufficiency is made as above. The specific diagnosis requires elevated serum levels of 17-OH progesterone.

Elevated plasma renin activity (PRA) indicates the presence of depleted intravascular volume and the need for higher doses of fludrocortisone replacement. Serum epinephrine levels are low in patients with adrenal insufficiency, since these patients do not have the high local concentrations of cortisol that are required to induce the enzyme PNMT in adrenal medulla for the synthesis of epinephrine from norepinephrine.
C. Imaging
When Addison disease is not clearly autoimmune, a chest radiograph is obtained to look for tuberculosis, fungal infection, or cancer as possible causes. CT scan of the abdomen will show small noncalcified adrenals in autoimmune Addison disease. The adrenals are enlarged in about 85% of cases due to metastatic or granulomatous disease. Calcification is noted in about 50% of cases of tuberculous Addison disease but is also seen with hemorrhage, fungal infection, pheochromocytoma, and melanoma.

Differential Diagnosis
Patients with secondary adrenal insufficiency (hypopituitarism) lack ACTH and have normal skin pigmentation, in contrast to patients with Addison disease who have elevated levels of ACTH that can increase skin pigmentation. Patients with ACTH deficiency have normal mineralocorticoid production and do not develop hyperkalemia. Addison disease should be considered in any patient with unexplained hypotension, but shock is usually caused by more common conditions such as gastrointestinal bleeding or sepsis. Hyponatremia or hyperkalemia may be seen in numerous other conditions (see Chapter 21). Drosperone, the progestin component in certain oral contraceptives, may cause hyperkalemia.

Unexplained weight loss, weakness, and anorexia may be mistaken for occult cancer. Nausea, vomiting, diarrhea, and abdominal pain may be misdiagnosed as intrinsic gastrointestinal disease. The hyperpigmentation may be confused with that due to ethnic or racial factors. Weight loss may simulate anorexia nervosa. The neurologic manifestations of Allgrove syndrome and adrenoleukodystrophy (especially in women) may mimic multiple sclerosis. Hemochromatosis also enters the differential diagnosis of skin hyperpigmentation, but it should be remembered that it may truly be a cause of Addison disease as well as diabetes mellitus and hypoparathyroidism. Serum ferritin is increased in most cases of hemochromatosis and is a useful screening test. About 17% of patients with AIDS have symptoms of cortisol resistance. AIDS can also cause frank adrenal insufficiency.

Hyperkalemia can be caused by isolated hypoaldosteronism and is seen in various conditions. Hyporeninemic hypoaldosteronism can be caused by renal tubular acidosis type IV and is commonly seen with diabetic nephropathy, hypertensive nephrosclerosis, tubulointerstitial diseases, and AIDS (see Chapter 21). Hyperreninemic hypoaldosteronism can be seen in patients with myotonic dystrophy, aldosterone synthase deficiency, and congenital adrenal hyperplasia. Hyperkalemia, hypertension, and hypogonadism may present as delayed adolescence or in adulthood in some patients with congenital adrenal hyperplasia (CYP17 deficiency); cortisol deficiency is also usually present but may not be clinically evident.

Complications
Any of the complications of the underlying disease (eg, tuberculosis) are more likely to occur, and the patient is susceptible to intercurrent infections that may precipitate crisis. Associated autoimmune diseases are common (see above).

Treatment
A. General Measures
Patients with Addison disease must be thoroughly informed about their condition. All infections should be treated immediately and vigorously, with the dose of hydrocortisone increased appropriately (see below). Patients are advised to wear a medical alert bracelet or medal reading, "Adrenal insufficiency—takes hydrocortisone."

B. Specific Therapy
Replacement therapy should include a combination of corticosteroids and mineralocorticoids. In mild cases, hydrocortisone alone may be adequate.

**Hydrocortisone** is the drug of choice. Most addisonian patients are well maintained on 15–30 mg of hydrocortisone orally daily in two divided doses, two-thirds in the morning and one-third in the late afternoon or early evening. Some patients respond better to prednisone in a dosage of about 2–4 mg orally in the morning and 1–2 mg in the evening. Adjustments in dosage are made according to the clinical response. A proper dose usually results in a normal WBC count differential.

The dose of corticosteroid should be raised in case of infection, trauma, surgery, stressful diagnostic procedures, or other forms of stress. The maximum hydrocortisone dose for severe stress is 50 mg intravenously or intramuscularly every 6 hours. Lower doses, oral or parenteral, are used for less severe stress. The dose is reduced back to normal as the stress subsides.

**Fludrocortisone acetate** has a potent sodium-retaining effect. The dosage is 0.05–0.3 mg orally daily or every other day. In the presence of postural hypotension, hyponatremia, or hyperkalemia, the dosage is increased. Similarly, in patients with fatigue, elevated PRA indicates the need for a higher replacement dose of fludrocortisone. If edema, hypokalemia, or hypertension ensues, the dose is decreased.

DHEA is given to some patients with adrenal insufficiency. In a double-blind clinical trial, patients taking DHEA 50 mg orally each morning experienced an improved sense of well-being, increased muscle mass, and a reversal in bone loss at the femoral neck. DHEA replacement did not improve fatigue, cognitive problems, or sexual dysfunction; however, its placebo effect may be significant in that regard. Older women who receive DHEA should be monitored for androgenic effects. Because over-the-counter preparations of DHEA have variable potencies, it is best to have the pharmacy formulate this with pharmaceutical-grade micronized DHEA.

Prognosis
The life expectancy of patients with Addison disease has been considered reasonably normal, as long as they are very compliant with taking their medications and are knowledgeable about their condition. However, a retrospective Swedish study of 1675 patients with Addison disease found an unexpected increase in all-cause mortality, mostly from cardiovascular disease, malignancy, and infectious causes. Associated conditions can pose additional health risks. For example, patients with adrenoleukodystrophy or Allgrove...
syndrome may suffer from neurologic disease. Patients with adrenal tuberculosis may have a serious systemic infection that requires treatment. Adrenal crisis can occur in patients who stop their medication or who experience stress such as infection, trauma, or surgery without appropriately higher doses of corticosteroids. Patients who take excessive doses of corticosteroid replacement can develop Cushing syndrome, which imposes its own risks.

Many patients with treated Addison disease complain of chronic low-grade fatigue.

Many patients with Addison disease do not feel entirely normal, despite glucocorticoid and mineralocorticoid replacement. This may be due, in part, to the inadequacy of oral replacement to duplicate cortisol’s normal circadian rhythm. Also, patients with Addison disease are deficient in epinephrine, but replacement epinephrine is not available. Fatigue may also be an indication of suboptimal dosing of medication, electrolyte imbalance, or concurrent problems such as hypothyroidism or diabetes mellitus. However, most patients with Addison disease are able to live fully active lives.

**General Considerations**

The term Cushing “syndrome” refers to the manifestations of excessive corticosteroids, commonly due to supra-physiologic doses of corticosteroid drugs and rarely due to spontaneous production of excessive corticosteroids by the adrenal cortex. Cases of spontaneous Cushing syndrome are rare (2.6 new cases yearly per million population) and have several possible causes.

About 40% of cases are due to Cushing “disease,” by which is meant the manifestations of hypercortisolism due to ACTH hypersecretion by the pituitary. Cushing disease is caused by a benign pituitary adenoma that is typically very small (< 5 mm) and usually located in the anterior pituitary (98%) or in the posterior pituitary (2%). It is at least three times more frequent in women than men. Excessive ingestion of gamma-hydroxybutyric acid (GHB, Xyrem) can also induce ACTH-dependent Cushing syndrome that resolves after the drug is stopped.

About 10% of cases are due to nonpituitary ACTH-secreting neoplasms (eg, small cell lung carcinoma), which produce excessive amounts of ectopic ACTH. Hypokalemia and hyperpigmentation are commonly found in this group.

About 15% of cases are due to ACTH from a source that cannot be initially located.

About 30% of cases are due to excessive autonomous secretion of cortisol by the adrenals—indipendently of ACTH, serum levels of which are usually low. Most such cases are due to a unilateral adrenal tumor. Benign adrenal adenomas are generally small and produce mostly cortisol; adrenocortical carcinomas are usually large when discovered and can produce excessive cortisol as well as androgens, with resultant hirsutism and virilization. ACTH-independent macronodular adrenal hyperplasia can also produce hypercortisolism due to the adrenal cortex cells’ abnormal stimulation by hormones such as catecholamines, arginine vasopressin, serotonin, hCG/LH, or gastric inhibitory polypeptide; in the latter case, hypercortisolism may be intermittent and food dependent and serum ACTH may not be completely suppressed. Pigmented bilateral adrenal macronodular adrenal hyperplasia is a rare cause of Cushing syndrome in children and young adults; it may be an isolated condition or part of the Carney complex.

**Clinical Findings**

**A. Symptoms and Signs**

Patients with Cushing syndrome usually have central obesity with a plethoric “moon face,” “buffalo hump,” supraclavicular fat pads, protuberant abdomen, and thin extremities. Muscle atrophy causes weakness, with difficulty standing up from a seated position or climbing stairs. Patients may also experience oligomenorrhea or amenorrhea (or erectile dysfunction in the male), backache, headache, hypertension, osteoporosis, avascular necrosis of bone, acne, and superficial skin infections. Patients may have thirst and polyuria (with or without glycosuria), renal calculi, glaucoma, purple striae (especially around the thighs, breasts, and abdomen), and easy bruisability. Unusual bacterial or fungal infections are common. Wound healing is impaired. Mental symptoms may range from diminished ability to concentrate to
increased lability of mood to frank psychosis. Patients are susceptible to opportunistic infections.

B. Laboratory Findings

Glucose tolerance is impaired as a result of insulin resistance. Polyuria is present as a result of increased free water clearance; diabetes mellitus with glycosuria may worsen it. Patients with Cushing syndrome often have leukocytosis with relative granulocytosis and lymphopenia. Hypokalemia may be present, particularly in cases of ectopic ACTH secretion.

Tests for Hypercortisolism

The easiest screening test for Cushing syndrome is the dexamethasone suppression test: dexamethasone 1 mg is given orally at 11 pm and serum is collected for cortisol determination at about 8 AM the next morning; a cortisol level < 5 mcg/dL (< 135 nmol/L, fluorimetric assay) or < 1.8 mcg/dL (< 49 nmol/L, high-performance liquid chromatography [HPLC] assay) excludes Cushing syndrome with some certainty. However, 8% of established patients with pituitary Cushing disease have dexamethasone-suppressed cortisol levels < 2 mcg/dL. Therefore, when other clinical criteria suggest hypercortisolism, further evaluation is warranted even in the face of normal dexamethasone-suppressed serum cortisol. Antiseizure drugs (eg, phenytoin, phenobarbital, primidone) and rifampin accelerate the metabolism of dexamethasone, causing a lack of cortisol suppression by dexamethasone. Estrogens—during pregnancy or as oral contraceptives or ERT—may also cause lack of dexamethasone suppressibility.

Patients with an abnormal dexamethasone suppression test require further investigation, which includes a 24-hour urine collection for free cortisol and creatinine. An abnormally high 24-hour urine free cortisol (or free cortisol to creatinine ratio of > 95 mcg cortisol/g creatinine) helps confirm hypercortisolism. A misleadingly high urine free cortisol excretion occurs with high fluid intake. In pregnancy, urine free cortisol is increased, while 17-hydroxycorticosteroids remain normal and diurnal variability of serum cortisol is normal. Carbamazepine and fenofibrate cause false elevations of urine free cortisol when determined by HPLC.

A midnight serum cortisol level > 7.5 mcg/dL is indicative of Cushing syndrome and distinguishes it from other conditions associated with a high urine free cortisol (pseudo-Cushing states). Requirements for this test include being in the same time zone for at least 3 days, being without food for at least 3 hours, and having an indwelling intravenous line established in advance for the blood draw.

Late-night salivary cortisol assays are useful due to the inconvenience of obtaining a midnight blood specimen for serum cortisol. Assays are available that use liquid chromatography-tandem mass spectrometry. Midnight salivary cortisol levels are normally < 0.15 mcg/dL (4.0 nmol/L). Midnight salivary cortisol levels that are consistently > 0.25 mcg/dL (7.0 nmol/L) are considered very abnormal. The late-night salivary cortisol test has a high sensitivity and specificity for Cushing syndrome, but false-positive and false-negative tests have occurred.

Interestingly, hypercortisolism without Cushing syndrome can occur in several conditions, such as severe depression, anorexia nervosa, alcoholism, and familial cortisol resistance.

Finding the Cause of Hypercortisolism

Once hypercortisolism is confirmed, a plasma or serum ACTH is obtained. It must be collected properly in a plastic tube on ice and processed quickly by a laboratory with a reliable, sensitive assay. A level of ACTH below about 20 pg/mL indicates a probable adrenal tumor, whereas higher levels are produced by pituitary or ectopic ACTH-secreting tumors.

Localizing Techniques

In ACTH-independent Cushing syndrome, CT of the adrenals usually detects a mass lesion. Most such lesions are benign adrenal adenomas, but an adrenal carcinoma is suspected in the following circumstances: (1) diameter ≥ 4 cm; (2) nodule growth; or (3) atypical imaging: density on noncontrast CT > 10 Hounsfield units (HU) or CT contrast washout ≥ 60% or relative contrast washout ≥ 40% at 15 minutes after intravenous administration.

In ACTH-dependent Cushing syndrome, MRI of the pituitary demonstrates a pituitary lesion in about 50% of cases. Premature cerebral atrophy is often noted. When the pituitary MRI is normal or shows a tiny (< 5 mm diameter) irregularity that may be incidental, selective catheterization of the inferior petrosal sinus veins draining the pituitary is performed. ACTH levels in the inferior petrosal sinus that are more than twice the simultaneous peripheral venous ACTH levels are indicative of pituitary Cushing disease. Inferior petrosal sinus sampling is also done during CRH administration, which ordinarily causes the ACTH levels in the inferior petrosal sinus to be over three times the peripheral ACTH level when the pituitary is the source of ACTH.

When inferior petrosal sinus ACTH concentrations are not above the requisite levels, a search for an ectopic source of ACTH is undertaken. Location of ectopic sources of ACTH commences with CT scanning of the chest and abdomen, with special attention to the lungs (for carcinoid or small cell carcinomas), the thymus, the pancreas, and the adrenals. In patients with ACTH-dependent Cushing syndrome, chest masses should not be assumed to be the source of ACTH, since opportunistic infections are common, so it is prudent to biopsy a chest mass to confirm the pathologic diagnosis prior to resection.

CT scanning fails to detect the source of ACTH in about 40% of patients with ectopic ACTH secretion. 111In-octreotide (OCT, somatostatin receptor scintigraphy) scanning is also useful in detecting occult tumors. A low-dose scan with 6 mCi OCT is used first; a high-dose scan with 12 mCi OCT may be used if the low-dose scan gives equivocal results. 18FDG-PET scanning is not usually helpful. Some ectopic ACTH-secreting tumors elude discovery, necessitating bilateral adrenalectomy. The ectopic source of ACTH should continue to be sought, since it may become detectable by OCT or CT scanning at a later date.
In non-ACTH-dependent Cushing syndrome, a CT scan of the adrenals can localize the adrenal tumor in most cases.

**Differential Diagnosis**

Alcoholic patients can have hypercortisolism and many clinical manifestations of Cushing syndrome. Pregnant women have elevated serum ACTH levels, increased urine free cortisol, and high serum cortisol levels due to high serum levels of cortisol-binding globulin. Regular use of the “party drug” gamma hydroxybutyrate (GHB, sodium oxybate) has been reported to cause reversible ACTH-dependent Cushing syndrome. Depressed patients also have hypercortisolism that can be nearly impossible to distinguish biochemically from Cushing syndrome but without clinical signs of Cushing syndrome. Some adolescents develop violaceous striae on the abdomen, back, and breasts; these are known as “striae distensae” and are not indicative of Cushing syndrome. Cushing syndrome can be misdiagnosed as anorexia nervosa (and vice versa) owing to the muscle wasting and extraordinarily high urine free cortisol levels found in anorexia. Patients with severe obesity frequently have an abnormal dexamethasone suppression test, but the urine free cortisol is usually normal, as is diurnal variation of serum cortisol. Patients with familial cortisol resistance have hyperandrogenism, hypertension, and hypercortisolism without actual Cushing syndrome. Patients with familial partial lipodystrophy type I develop central obesity and moon facies, along with thin extremities and central obesity with a dorsocervical fat pad (“buffalo hump”) that may mimic Cushing syndrome.

**Complications**

Cushing syndrome, if untreated, produces serious morbidity and even death. The patient may suffer from any of the complications of hypertension or of diabetes mellitus. Susceptibility to infections is increased. Compression fractures of the osteoporotic spine and aseptic necrosis of the femoral head may cause marked disability. Nephrolithiasis and psychosis may occur. Following bilateral adrenalectomy for Cushing disease, a pituitary adenoma may enlarge progressively, causing local destruction (eg, visual field impairment) and hyperpigmentation; this complication is known as Nelson syndrome.

**Treatment**

Cushing disease is best treated by transsphenoidal selective resection of the pituitary adenoma. After pituitary surgery, the rest of the pituitary usually returns to normal function; however, the pituitary corticotrophs remain suppressed and require 6–36 months to recover normal function. Hydrocortisone or prednisone replacement therapy is necessary in the meantime. Patients who do not have a remission (or who have a recurrence) may be considered for treatment with cabergoline 0.5–3.5 mg orally twice weekly, which was successful in 40% of patients in one small study. Laparoscopic adrenalectomy should be offered to unresponsive patients. Another treatment option for patients with ACTH-secreting pituitary tumors is stereotactic pituitary radiosurgery (gamma knife or Cyberknife), which normalizes urine free cortisol in two-thirds of patients within 12 months. Conventional radiation therapy results in a 23% cure rate. Pasireotide, a novel multireceptor-targeting somatostatin analog that has not yet received approval by the US FDA, is a potential treatment for refractory Cushing disease. Pasireotide (600–900 mcg subcutaneously twice daily) normalizes the urine free cortisol in at least 17% of patients with Cushing disease.

Pituitary radiosurgery can also be used to treat Nelson syndrome, the progressive enlargement of ACTH-secreting pituitary tumors following bilateral adrenalectomy. Patients who are not surgical candidates may be given a trial of ketoconazole in doses of about 200 mg orally every 6 hours; liver enzymes must be monitored for progressive elevation.

Adrenal neoplasms secreting cortisol are resected laparoscopically, if they are < 6 cm diameter. Postoperatively, the contralateral adrenal’s cortisol secretion is deficient, due to ACTH suppression, so postoperative hydrocortisone replacement is required until recovery occurs.

Patients with metastatic adrenocortical carcinoma have detectable cortisol levels following removal of the primary tumor. Metastases may not be visible on scanning. Patients with adrenal carcinoma should be treated postoperatively with mitotane for a course of 2–5 years, since it appears to improve prognosis (see below). Mitotane is given, beginning with 0.5 g twice daily with meals and increasing to 1 g twice daily within 2 weeks. The doses of mitotane are adjusted every 2–3 weeks ideally to reach serum levels of 14–20 mcg/mL; however, only about half the patients can tolerate mitotane levels above 14 mcg/mL. Mitotane side effects include CNS depression, lethargy, hypogonadism, hypercholesterolemia, hypocalcemia, hepatotoxicity, leukopenia, hypertension, nausea, rash, TSH suppression with hypothyroidism, and primary adrenal insufficiency. Replacement hydrocortisone or prednisone should be started when mitotane doses reach 2 g daily. The replacement dose of hydrocortisone starts at 15 mg in the morning and 10 mg in the afternoon, but must often be doubled or tripled because mitotane increases cortisol metabolism and cortisol binding globulin levels; the latter can artifically raise serum cortisol levels. Ketoconazole or metyrapone can help suppress hypercortisolism in unresectable adrenal carcinoma.

Ectopic ACTH-secreting tumors should be located, when possible, and surgically resected. If that cannot be done, laparoscopic bilateral adrenalectomy is usually recommended. Medical treatment with a combination of mitotane (3–5 g/24 h), ketoconazole (0.4–1.2 g/24 h), and metyrapone (3–4.5 g/24 h) often suppresses the hypercortisolism. Octreotide LAR, 20–40 mg injected intramuscularly every 28 days, suppresses ACTH secretion in about one-third of such cases.

Patients who are successfully treated for Cushing syndrome typically develop “cortisol withdrawal syndrome,” even when given replacement corticosteroids for adrenal
insufficiency. Manifestations can include hypotension, nausea, fatigue, arthralgias, myalgias, pruritus, and flaking skin. Increasing the hydrocortisone replacement to 30 mg orally twice daily can improve these symptoms; the dosage is then reduced slowly as tolerated. Patients with Cushing syndrome are prone to develop osteoporosis. Bone densitometry is recommended for all patients and treatment is commenced for patients with osteoporosis. (See Osteoporosis section, above.)

Prognosis

The manifestations of Cushing syndrome regress with time, but patients are often left with residual mild cognitive impairment, muscle weakness, osteoporosis, and sequelae from vertebral fractures. Younger patients have a better chance for recovery and children with short stature may have catch-up growth following cure.

Patients with Cushing syndrome from a benign adrenal adenoma experience a 5-year survival of 95% and a 10-year survival of 90%, following a successful adrenalectomy. Patients with Cushing disease from a pituitary adenoma experience a similar survival if their pituitary surgery is successful, which can be predicted if the postoperative nonsuppressed serum cortisol is < 2 mcg/dL. However, transsphenoidal surgery incurs a failure rate of about 10–20%, often due to the adenoma's ectopic position or invasion of the cavernous sinus. Those patients who have a complete remission after transsphenoidal surgery have about a 15–20% chance of recurrence over the next 10 years. Patients with failed pituitary surgery may require pituitary radiation therapy, which has its own morbidity. Laparoscopic bilateral adrenalectomy may be required; recurrence of hypercortisolism may occur as a result of growth of an adrenal remnant stimulated by high levels of ACTH. The prognosis for patients with ectopic ACTH-producing tumors depends on the aggressiveness and stage of the particular tumor. Patients with ACTH of unknown source have a 5-year survival rate of 65% and a 10-year survival rate of 55%.

In patients with adrenocortical carcinoma, the prognosis depends on the stage of the tumor at the time of surgery. In patients with stage I–II disease, confined to the adrenal by surgical inspection and scan, the median 5-year survival is about 60% and long-term survival does occur. However, despite apparent complete resection in stage I–III tumors, visible metastases develop in about 40% of patients within 2 years. Adjuvant therapy with mitotane appears to improve the prognosis, with patients receiving mitotane having a 5-year survival of 87% versus 53% in those not receiving mitotane. Patients with advanced stage IV disease at the time of surgery have a poorer prognosis but debulking surgery and therapy with mitotane may be beneficial.

Hirsutism & Virilization

General Considerations

Hirsutism is defined as cosmetically unacceptable terminal hair growth that appears in women in a male pattern. Some degree of hirsutism affects about 5–10% of non-Asian women of reproductive age. The amount of hair growth deemed unacceptable depends on a woman’s ethnicity and familial and cultural norms. Hirsutism is quantitated using the Ferriman-Gallwey score in which hirsutism is graded from 0 (none) to 4 (severe) in nine areas of the body with a score of 10 or more deemed unacceptable.

Etiology

Hirsutism may be idiopathic or familial or be caused by the following disorders: polycystic ovary syndrome (PCOS), steroidogenic enzyme defects, neoplastic disorders; or rarely by medications, acromegaly, or ACTH-induced Cushing disease.

A. Idiopathic or Familial

Most women with hirsutism or androgenic alopecia have no detectable hyperandrogenism. Patients often have a
B. Polycystic Ovary Syndrome (Hyperthecosis, Stein–Leventhal Syndrome)

PCOS is a common functional disorder of the ovaries, affecting about 4–6% of premenopausal women in the United States and accounting for at least 50% of all cases of hirsutism associated with elevated testosterone levels. It is familial and transmitted as a modified autosomal dominant trait. Affected women have elevated serum testoster-

one or free testosterone levels. Affected women have signs of androgen excess, including hirsutism, acne, and male-pattern thinning of scalp hair. About 50% of affected women have oligomenorrhea or amenorrhea with anovula-
tion. Despite the syndrome’s name, the presence of ovar-
ian cysts is not helpful diagnostically and is actually a misnomer, since about 30% of women with PCOS do not have cystic ovaries and 25–30% of normal menstruating women have cystic ovaries. Obesity and high serum insulin levels (due to insulin resistance) contribute to the syn-
drome in 70% of women. The serum LH:FSH ratio is often > 2.0. Both adrenal and ovarian androgen hypersecretion are commonly present. Women with PCOS have a 35% risk of depression, compared with 11% in age-matched controls. Diabetes mellitus is present in about 13% of cases. Obstructive sleep apnea is particularly common, even in slender women with PCOS. Untreated women with amen-
orrrhea have a slightly increased risk of endometrial carcino-
noma. Hypertension and hyperlipidemia are often present, increasing the risk of cardiovascular disease. Women frequently regain normal menstrual cycles with aging.

C. Steroidogenic Enzyme Defects

Baby girls with “classic” 21-hydroxylase deficiency have ambiguous genitalia and may become virilized unless treated with corticosteroid replacement; about 50% of such patients have clinically evident mineralocorticoid deficiency (salt-wasting) as well.

About 2% of patients with adult-onset hirsutism have been found to have a partial defect in adrenal 21-hydroxylase. The condition is more common in Ashkenazi Jews, Yupic Alaskans, and natives of La Reunion Island. The phenotypic expression is delayed until adolescence or adulthood; such patients do not have salt-wasting. Polycystic ovaries and ad-

renal adenomas are more likely to develop in these women.

Some rare patients with hyperandrogenism and hyper-
tension have 11-hydroxylase deficiency. This is distin-
guished from cortisol resistance by high cortisol serum levels in the latter and by high serum 11-deoxycorticisol levels in the former.

Patients with an XY karyotype and a deficiency in 17β-hydroxysteroid dehydrogenase-3 or a deficiency in 5α-reductase-2 may present as phenotypic girls in whom virilization develops at puberty.

D. Neoplastic Disorders

Ovarian tumors are very uncommon causes of hirsutism (0.8%) and include arrhenoblastomas, Sertoli-Leydig cell tumors, dysgerminomas, and hilar cell tumors. Adrenal carcinoma is a rare cause of Cushing syndrome and hyper-

androgenism that can be quite virilizing. Pure androgen-

secreting adrenal tumors occur very rarely; about 50% are malignant.

E. Rare Causes of Hirsutism

Acromegaly and ACTH-induced Cushing syndrome can cause hirsutism. Porphyria cutanea tarda can cause perior-

bital hair growth in addition to dermatitis in sun-exposed areas. Maternal virilization during pregnancy may occur as a result of a luteoma of pregnancy, hyperreactio luteinalis, or polycystic ovaries. In postmenopausal women, diffuse stromal Leydig cell hyperplasia is a rare cause of hyperan-

drogenism. Acquired hypertrichosis lanuginosa is mani-
fested by the appearance of diffuse fine lanugo hair growth on the face and body along with stomatologic symptoms; the disorder is usually associated with an internal malign-

ancy, especially colorectal cancer, and may regress after tumor removal. Pharmacologic causes include minoxidil, cyclosporine, phenytoin, anabolic steroids, diazoxide, and certain progestins.

Clinical Findings

A. Symptoms and Signs

Modest androgen excess from any source increases sexual hair (chin, upper lip, abdomen, and chest) and increases sebaceous gland activity, producing acne. Menstrual irregular-

arities, anovulation, and amenorrhea are common. If androgen excess is pronounced, defeminization (decrease in breast size, loss of feminine adipose tissue) and viriliza-
tion (frontal balding, muscularity, clitoromegaly, and deepening of the voice) occur. Virilization points to the presence of an androgen-producing neoplasm.

Hypertension may be seen in rare patients with Cushing syndrome, adrenal 11-hydroxylase deficiency, or cortisol resistance syndrome.

A pelvic examination may disclose clitoromegaly or ovarian enlargement that may be cystic or neoplastic.

B. Laboratory Testing and Imaging

Serum androgen testing is mainly useful to screen for rare occult adrenal or ovarian neoplasms. Some general guide-

lines are presented here, though exceptions are common.

Serum is assayed for total testosterone and free testoster-
one. A serum testosterone level > 200 ng/dL or free testoster-
one > 40 ng/dL indicates the need for pelvic examination and ultrasound. If that is negative, an adrenal CT scan is performed.

Most radioimmunoassays and enzyme-linked immuno-

sorbent assay (ELISA) for testosterone are inaccurate below serum testosterone levels of 300 ng/dL. The more accurate testosterone assays rely upon extraction and chro-

matography, followed by mass spectrometry or immunoas-
say. Free testosterone is best measured by calculation, using
Accurate assays for testosterone and sex hormone binding globulin.

A serum androstenedione level > 1000 ng/dL also points to an ovarian or adrenal neoplasm.

Patients with milder elevations of serum testosterone or androstenedione usually are treated with an oral contraceptive.

Patients with very elevated serum DHEAS (> 700 mcg/dL) have an adrenal source of androgen. This usually is due to adrenal hyperplasia and rarely to adrenal carcinoma. An adrenal CT scan is performed.

No firm guidelines exist as to which patients (if any) with hyperandrogenism should be screened for “late-onset” 21-hydroxylase deficiency. The evaluation requires levels of serum 17-hydroxyprogesterone to be drawn at baseline and at 30–60 minutes after the intramuscular injection of 0.25 mg of cosyntropin (ACTH1–24). This test should ideally be done during the follicular phase of a woman’s menstrual cycle. Patients with congenital adrenal hyperplasia will usually have a baseline 17-hydroxyprogesterone level over 300 ng/dL or a stimulated level over 1000 ng/dL. Patients with any clinical signs of Cushing syndrome should receive a screening test. (See Cushing Syndrome.)

Serum levels of FSH and LH are elevated if amenorrhea is due to ovarian failure. An LH:FSH ratio > 2.0 is common in patients with PCOS. On abdominal ultrasound, about 25–30% of normal young women have polycystic ovaries, so the appearance of ovarian cysts on ultrasound is not helpful. Pelvic ultrasound or MRI can usually detect virilizing tumors of the ovary. However, small virilizing ovarian tumors may not be detectable on imaging studies; selective venous sampling for testosterone may be used for diagnosis in such patients.

### Treatment

Postmenopausal women with severe hyperandrogenism should undergo laparoscopic bilateral oophorectomy (if CT scan of the adrenals and ovaries is normal), since small hilar cell tumors of the ovary may not be visible on scans. Girls with classic salt-wasting congenital adrenal hyperplasia and infertility or treatment-resistant hyperandrogenism may be treated with laparoscopic bilateral adrenalectomy. Any drugs causing hirsutism are stopped.

**Spironolactone** may be taken in doses of 50–100 mg orally twice daily on days 5–25 of the menstrual cycle or daily if used concomitantly with an oral contraceptive. Hyperkalemia and other side effects are uncommon.

**Finasteride** inhibits 5α-reductase, the enzyme that converts testosterone to active dihydrotestosterone in the skin. Given as 2.5-mg doses orally daily, it provides modest reduction in hirsutism over 6 months—somewhat less than that achieved with spironolactone. Finasteride is ineffective for androgenic alopecia in women. Side effects are rare.

**Flutamide** inhibits testosterone binding to androgen receptors and also suppresses serum testosterone. It is given orally in a dosage of 250 mg/d for the first year and then 125 mg/d for maintenance. Used with an oral contraceptive, it appears to be more effective than spironolactone in improving hirsutism, acne, and male pattern baldness. Women with congenital adrenal hyperplasia who take replacement hydrocortisone experience decreased renal cortisol clearance when treated with flutamide, resulting in lower hydrocortisone dosage requirements; corticosteroid replacement doses should be reduced when flutamide is added for treatment of hirsutism. Hepatotoxicity has been reported but is rare.

Oral contraceptives stimulate menses (if that is desired) and reduce acne vulgaris. They are not very effective for hirsutism, but increase serum sex hormone binding globulin and thereby slightly reduce serum free testosterone levels. Oral contraceptives containing antiandrogen progestins include desogestrel (Azette, Kariva), drospirenone (Gianvi), or norgestimate (Ortho Tri-Cyclen Lo). Cyproterone is a particularly potent antiandrogen that is not available in the United States but is available as Diane-35 in Canada and the United Kingdom. These preparations may be more effective for treating hirsutism but are associated with an increased risk of deep venous thrombosis.

**Metformin** may improve menstrual function in women with PCOS and amenorrhea or oligomenorrhea but is less effective than oral contraceptives. Metformin is not effective in promoting fertility or in improving hirsutism in women with PCOS. Metformin therapy is usually given with meals and is started at a dose of 500 mg/d with breakfast for 1 week, then 500 mg with breakfast and dinner for 1 week, then 500 mg with breakfast and 1000 mg with dinner for 1 week, then 850–1000 mg with breakfast and dinner. The most common side effects are dose-related gastrointestinal upset and diarrhea. Patients are advised to take the highest tolerated dosage. Metformin appears to be nonteratogenic. Although metformin reduces insulin resistance, it does not cause hypoglycemia in nondiabetics. Metformin is contraindicated in renal and hepatic disease.

**Simvastatin** can reduce hirsutism in women with PCOS. In one study, simvastatin 20 mg orally daily was given to women receiving an oral contraceptive for PCOS. Besides improving their serum lipid profiles, women receiving simvastatin had greater decreases in hirsutism and serum free testosterone levels than the women receiving an oral contraceptive alone.

**Clomiphene** is the treatment of choice for women with PCOS and infertility. Over 6 months, clomiphene therapy resulted in a 22.5% rate of conception with live births. The rate of pregnancy with multiple fetuses is 6%.

Women with classic congenital adrenal hyperplasia (21-hydroxylase deficiency) have hirsutism and adrenal insufficiency that requires glucocorticoid and mineralocorticoid replacement. However, women with partial “late onset” 21-hydroxylase deficiency do not require hormone replacement. Treating such women with dexamethasone risks iatrogenic Cushing syndrome and is not particularly more effective than the other treatments for hirsutism listed below.

**Local treatment** by shaving or depilatories, waxing, electrolysis, or bleaching should be encouraged. **Eflornithine** (Vaniqa 13.9%) topical cream retards hair growth when applied twice daily to unwanted facial hair; improvement is noted within 4–8 weeks. However, local skin irritation may occur. Hirsutism returns with discontinuation. **Laser therapy** (photoepilation) is a fairly effective treatment for facial hirsutism, particularly for women with dark hair and
light skin; longer-wavelength lasers are used for women with darker skin. Complications of laser therapy include skin hypopigmentation (rare) and hyperpigmentation, which occurs in 20% but usually resolves; a paradoxical increase in hair growth occurs infrequently. Repeated laser treatments are usually required.

**Topical minoxidil**, 2% solution applied twice daily to a dry scalp, may be used to effectively treat women with androgenic alopecia. Hypertrichosis is an unwanted side effect of topical minoxidil, occurring in 3–5% of treated women; it may affect the forehead, cheeks, upper lip, or chin. Hypertrichosis resolves within 1–6 months after the drug is stopped.

Antiandrogen treatments must be given only to non-pregnant women. Women must be counseled to take oral contraceptives, when indicated, and avoid pregnancy, since use during pregnancy causes malformations and pseudohermaphroditism in male infants.

### PRIMARY ALDOSTERONISM

#### ESSENTIALS OF DIAGNOSIS

- Hypertension that may be severe or drug-resistant.
- Hypokalemia (in minority of patients) may cause polyuria, polydipsia, muscle weakness.
- Elevated plasma and urine aldosterone levels and low plasma renin level.

#### General Considerations

Primary aldosteronism (hyperaldosteronism) causes hypertension by an inappropriately high aldosterone secretion that does not suppress adequately with sodium loading. Primary aldosteronism is believed to account for 8% of all cases of hypertension and 20% of cases of resistant hypertension. It may be difficult to distinguish primary aldosteronism from cases of low renin essential hypertension, with which it may overlap. Patients of all ages may be affected, but the peak incidence is between 30 years and 60 years. Excessive aldosterone production increases sodium retention and suppresses plasma renin. It increases renal potassium excretion, which can lead to hypokalemia. Cardiovascular events are more prevalent in patients with aldosteronism (35%) than in those with essential hypertension (11%). Primary aldosteronism may be caused by an aldosterone-producing adrenal adenoma (Conn syndrome), 40% of which have been found to have somatic mutations in a gene involved with the potassium channel. Primary aldosteronism is also commonly caused by unilateral or bilateral adrenal hyperplasia. Bilateral aldosteronism may be corticosteroid suppressible, due to an autosomal-dominant genetic defect allowing ACTH stimulation of aldosterone production.

#### Clinical Findings

**A. Symptoms and Signs**

Patients have hypertension that is typically moderate. Some patients have only diastolic hypertension, without other symptoms and signs. Edema is rarely seen in primary aldosteronism. About 37% of patients have hypokalemia and may consequently have symptoms of muscular weakness (at times with paralysis simulating periodic paralysis), paresthesias with frank tetany, headache, polyuria, and polydipsia.

**B. Laboratory Findings**

Screening for hyperaldosteronism is usually with PRA. About 20% of hypertensive patients have a low PRA, and a significant portion of these patients have primary aldosteronism. Initial screening can also include both aldosterone and plasma renin activity to determine an aldosterone to renin ratio (see below).

Plasma potassium should also be determined in hypertensive individuals. However, hypokalemia, once thought to be the hallmark of hyperaldosteronism, is present in only 37% of affected patients: 50% of those with an adrenal adenoma and 17% of those with adrenal hyperplasia. Proper phlebotomy technique is important to avoid spurious increases in potassium. The blood should be drawn slowly with a syringe and needle (rather than a vacutainer) at least 5 seconds after tourniquet release and without fist-clenching. Plasma potassium, rather than the routine serum potassium, should be measured in cases of unexpected hyperkalemia, with the separation of plasma from cells within 30 minutes of collection. Besides hypokalemia, many patients with primary aldosteronism have metabolic alkalosis with an elevated serum bicarbonate (HCO₃⁻) concentration.

Testing for primary aldosteronism should be done for all hypertensive patients with hypokalemia, whether spontaneous or diuretic induced. But since only a minority of affected patients have hypokalemia, testing should also be considered for normokalemic hypertensive patients with (1) treatment-resistant hypertension (despite three drugs); (2) severe hypertension: > 160 mm Hg systolic or > 100 mm Hg diastolic; (3) early-onset hypertension; (4) low-renin hypertension; (5) hypertension with an adrenal mass; and (6) family history of aldosteronism.
For a patient to be properly tested for primary aldosteronism, certain antihypertensive medications should ideally be held. Diuretics should be discontinued for 3 weeks. Dihydropyridine calcium channel blockers can normalize aldosterone secretion, thus interfering with the diagnosis. β-Blockers suppress PRA in patients with essential hypertension. Antihypertensive medications that have minimal effects on the plasma aldosterone:renin ratio include ACE inhibitors, α-blockers, verapamil, hydralazine, prazosin, doxazosin, and terazosin. However, it may be impractical to hold or change antihypertensive medicines; in such cases, testing should proceed.

During the testing period, the patient should have an unrestricted high sodium intake. The patient should be out of bed for at least 2 hours and seated for 5–15 minutes before the blood draw, which should preferably be obtained between 8 AM and 10 AM. Renin is measured as either PRA or direct renin concentration. Serum aldosterone should ideally be measured with a tandem mass spectrometry assay.

For patients who have not been receiving diuretics for at least 3 weeks, a plasma renin activity (PRA) that is normal or elevated makes primary aldosteronism very unlikely. However, a low PRA alone cannot establish the diagnosis of primary aldosteronism, since it occurs in many patients with essential hypertension. An aldosterone:renin ratio is a sensitive screening test. Serum aldosterone (ng/dL):PRA (ng/mL/h) ratios < 24 exclude primary aldosteronism, whereas ratios between 24 and 67 are suspicious and ratios > 67 are very suggestive of primary aldosteronism. Such elevated ratios are not diagnostic; rather, they indicate the need to document increased aldosterone secretion with a 24-hour urine collection. Another problem with the aldosterone:renin ratio is the use of different units and measurements. For aldosterone, 1 ng/dL converts to 27.7 pmol/L. For renin, a PRA of 1 ng/mL/h (12.8 pmol/L/min) converts to a direct renin concentration of 5.2 ng/L (8.2 μU/L).

When the aldosterone:renin ratio is high, a 24-hour urine collection is assayed for aldosterone, free cortisol, and creatinine. A low PRA (< 5 mcg/L/h) with a urine aldosterone over 20 mcg/24 h indicates primary aldosteronism.

Once primary aldosteronism is diagnosed, unilateral adrenal aldosteronism may be distinguished from bilateral adrenal aldosteronism by adrenal vein sampling and by further biochemical testing. Plasma may be assayed for 18-hydroxycorticosterone; a level > 100 ng/dl is seen with adrenal neoplasms, whereas levels < 100 ng/dl are nondiagnostic. In addition, a posture stimulation test may be performed, but this requires overnight hospitalization. The test is performed by drawing blood for aldosterone at 8 AM while the patient is supine after overnight recumbency and again after the patient is upright for 4 hours. Patients with a unilateral adrenal adenoma usually have a baseline plasma aldosterone level > 20 ng/dl that does not rise. Patients with bilateral adrenal hyperplasia typically have a baseline plasma aldosterone level < 20 ng/dl that rises during upright posture. The accuracy of the posture stimulation test is about 85%.

C. Imaging

All patients with biochemically confirmed primary aldosteronism require a thin-section CT scan of the adrenals to screen for a rare adrenal carcinoma. In the absence of a large adrenal carcinoma, adrenal CT scanning cannot reliably distinguish unilateral from bilateral aldosterone excess, having a sensitivity of 78% and a specificity of 78% for unilateral aldosteronism. Therefore, the decision to perform a unilateral adrenalectomy should not be based solely on an adrenal CT scan. Instead, patients with primary aldosteronism should be considered for a trial of medical therapy with spironolactone or eplerenone. If medical therapy is ineffective or if surgery is desired for an apparent adrenal adenoma, further evaluation for surgical candidacy should be done with laboratory testing. However, since CT scanning and laboratory testing are often inconclusive, adrenal vein sampling is often required.

D. Adrenal Vein Sampling

Bilateral selective adrenal vein sampling is the most accurate way to determine whether primary aldosteronism is due to unilateral aldosterone excess, which can be treated by adrenalectomy. It is indicated only to direct the surgeon to the correct adrenal and should be performed only if surgery is contemplated. It is particularly useful for patients who are not hypokalemic, who are over age 40 years, or who have an adrenal adenoma < 1 cm diameter. It is particularly difficult to catheterize the right adrenal vein. Therefore, the venous samples are assayed for both aldosterone and cortisol during a cosyntropin (ACTH₁–24) infusion to be sure that the sampling has included both adrenal veins. The procedure has a sensitivity of 95% and a specificity of 100% but only when performed by an experienced radiologist. The complication rate is 2.5%. Risks can be minimized if the radiologist avoids adrenal venography and limits the use of contrast.

> Screening

Hyperaldosteronism is the most common cause of refractory hypertension in youth and middle-aged adults. The Endocrine Society’s Clinical Practice Guidelines recommend screening for hyperaldosteronism in patients who have any of the following: (1) blood pressure > 160/100 mm Hg; (2) drug-resistant hypertension; (3) hypertension with spontaneous or diuretic-induced hypokalemia; (4) hypertension with adrenal incidentaloma; (5) hypertension with a family history of early-onset hypertension or cerebrovascular accident before age 40 years; (6) hypertension and a first-degree relative with primary aldosteronism.

> Differential Diagnosis

The differential diagnosis of primary aldosteronism includes other causes of hypokalemia (see Chapter 21) in patients with essential hypertension, especially diuretic therapy. Chronic depletion of intravascular volume stimulates renin secretion and secondary hyperaldosteronism. Thus, it is important to discontinue diuretics and ensure adequate hydration and sodium intake when assessing a patient for primary hyperaldosteronism.

Excessive ingestion of real licorice (black and derived from anise) or Sambuca (an Italian liqueur) can cause hypertension and hypokalemia. Real licorice and anise-flavored
drinks (sambuca, pastis) contain glycyrrhizinic acid, which has a metabolite that inhibits the adrenal enzyme 11β-hydroxysteroid dehydrogenase type 2 that normally inactivates cortisol in the renal tubule. Higher renal tubular cortisol levels activate aldosterone receptors, resulting in renal tubular absorption of sodium and excretion of potassium. Oral contraceptives may increase aldosterone secretion in some patients. Renal vascular disease can cause severe hypertension with hypokalemia; PRA is high, distinguishing it from primary aldosteronism.

Excessive adrenal secretion of other corticosteroids (besides aldosterone) may also cause hypertension with hypokalemia. This occurs with certain congenital adrenal enzyme disorders such as P450c11 deficiency (increased deoxycorticosterone with virilization and deficient cortisol) or P450c17 deficiency (increased deoxycorticosterone, corticosterone, and progesterone but deficient estradiol and testosterone). P450c17 deficiency results from a defect in the 17-hydroxylase enzyme in both the adrenal and ovarian steroidogenic pathways. Presenting signs include hypertension and ambiguous genitalia or primary amenorrhea. Urinary aldosterone secretion is <20 mcg/24 h and plasma renin is low in both P450c11 and P450c17 deficiencies. Primary cortisol resistance can cause hypertension and hypokalemia; renin and aldosterone are suppressed, while plasma levels of cortisol, ACTH, and deoxycorticosterone are high. Liddle syndrome is an autosomal dominant cause of hypertension and hypokalemia resulting from excessive sodium absorption from the renal tubule; renin and aldosterone levels are low. Thyrotoxicosis and familial periodic paralysis may also present with hypokalemia. Hyperaldosteronism may rarely be due to a malignant ovarian tumor.

Complications

The incidence of cardiovascular complications from hypertension are higher in primary aldosteronism than in idiopathic hypertension. Following unilateral adrenalectomy for Conn syndrome, suppression of the contralateral adrenal may result in temporary postoperative hypoaldosteronism, characterized by hyperkalemia and hypotension.

Treatment

Conn syndrome (unilateral aldosterone-secreting adrenal adenoma) is treated by laparoscopic adrenalectomy, though long-term therapy with spironolactone or eplerenone is an option. Bilateral adrenal hyperplasia is best treated with spironolactone or eplerenone. Spironolactone also has antiandrogen activity and frequently causes breast tenderness, gynecomastia, or reduced libido; it is given at initial doses of 12.5–25 mg orally once daily; the dose may be titrated upward to 200 mg daily. Eplerenone is becoming favored for men, since it does not have antiandrogen effects; however, it has a short half-life and must be given twice daily in oral doses of 25–50 mg. Blood pressure must be monitored daily when beginning these antimineralocorticoid medications; significant drops in blood pressure have occurred when these drugs are added to other antihypertensives. Other antihypertensive drugs may also be required. Glucocorticoid-removable aldosteronism is very rare but may respond well to suppression with low-dose dexamethasone.

Prognosis

The hypertension is reversible in about two-thirds of cases but persists or returns in spite of surgery in the remainder. The prognosis is much improved by early diagnosis and treatment. Only 2% of aldosterone-secreting adrenal tumors are malignant.

ESSENTIALS OF DIAGNOSIS

PHEOMCROMOCYTOMA & PARAGANGLIOMA

- “Attacks” of headache, perspiration, palpitations, anxiety.
- Hypertension, frequently sustained but often paroxysmal, especially during surgery or delivery.
- Elevated urinary catecholamines or their metabolites. Normal serum T₄ and TSH.

General Considerations

Both pheochromocytomas and non–head-neck paragangliomas are tumors of the sympathetic nervous system. Pheochromocytomas arise from the adrenal medulla and usually secrete both epinephrine and norepinephrine. Paragangliomas (“extra-adrenal pheochromocytomas”) arise from sympathetic paraganglia, often metastasize, and secrete norepinephrine or are nonsecretory. Excessive levels of norepinephrine or neuropeptide Y cause hypertension, while epinephrine causes tachyarrhythmias. These tumors may be located in either or both adrenals or anywhere along the sympathetic nervous chain, and rarely in such aberrant locations as the mediastinum, heart, or bladder.

These rare tumors are deceptive and deadly. They are a rare cause of hypertension, being found in <0.3% of hypertensive individuals. The incidence is higher in patients...
with moderate to severe hypertension. About two to three new cases per million population are diagnosed annually. However, in autopsy cases, the incidence of pheochromocytoma is 250–1300 cases per million, indicating that most cases are not diagnosed during life.

About 25% of patients with pheochromocytomas/paragangliomas harbor germline mutations making them prone to develop the tumor. The chance of harboring a germline mutation is nearly 100% in patients with a family history of pheochromocytomas/paragangliomas and 17% in patients without any known family history of these tumors; cystadenomas of the adnexa or epididymis; renal cysts, adenomas, and carcinomas); inheritance is autosomal dominant. Patients with VHL develop pheochromocytomas that are less likely to be extra-adrenal, less likely to be malignant (3.5%), more likely to be bilateral, and more likely to present at an early age. Pheochromocytomas that arise in patients with VHL secrete exclusively norepinephrine and its metabolite normetanephrine. Therefore, individuals who carry type 2 VHL mutations should be screened for pheochromocytoma with plasma normetanephrine levels.

MEN 2A is associated with pheochromocytomas and medullary thyroid carcinoma. MEN 2B is associated with pheochromocytomas, aggressive medullary thyroid carcinoma, mucosal neuromas, and marfinooid habitus. von Recklinghausen neurofibromatosis type 1 (NF-1) is associated with an increased risk of pheochromocytomas/paragangliomas as well as cutaneous neurofibromas, optic gliomas, vascular anomalies, hamartomas, malignant nerve sheath tumors, and smooth-bordered café au lait spots. Familial paraganglioma can be caused by mutations in the genes encoding suscinate dehydrogenase (SDH) subunits B, C, or D. Patients with such germline mutations are more apt to have bilateral pheochromocytomas or multicentric paragangliomas.

**Clinical Findings**

**A. Symptoms and Signs (Table 26–12)**

Pheochromocytomas can be lethal unless they are diagnosed and treated appropriately. Catastrophic hypertensive crisis and fatal cardiac arrhythmias can occur spontaneously or may be triggered by intravenous contrast dye or glucagon injection, needle biopsy of the mass, anesthesia, or surgical procedures. Paroxysms can be triggered by exercise, bending, lifting, or emotional stress. Certain drugs can precipitate attacks: monoamine oxidase (MAO) inhibitors, caffeine, nicotine, decongestants, amphetamines, cocaine, ionic intravenous contrast, and epinephrine. Bladder paragangliomas may present with paroxysms during micturition.

Paroxysms typically produce hypertension (90%) and such symptoms as severe headache (80%), perspiration (70%), and palpitations (60%); other symptoms may include anxiety (50%), a sense of impending doom, or tremor (40%). Vasomotor changes during an attack cause mottled cyanosis and facial pallor; as the attack subsides, facial flushing may occur as a result of reflex vasodilation. Epinephrine secretion by an adrenal pheochromocytoma may cause episodic tachyarrhythmias, hypotension, or even syncope. Acute coronary syndrome can be caused by coronary vasoconstriction. Confusion, psychosis, seizures, transient ischemic attacks, or stroke may occur with cerebrovascular vasoconstriction or hemorrhagic stroke. Aortic aneurysms may dissect and rupture. Abdominal pain, nausea, vomiting, and even ischemic bowel can be due to splanchnic vasoconstriction. Large or hemorrhagic abdominal tumors can also cause abdominal pain. Peripheral vasoconstriction can cause Raynaud phenomenon or even gangrene. Patients may experience nervousness and irritability, increased appetite, and loss of weight. Other patients have pulmonary edema and heart failure due to cardiomyopathy. Cytokine release can cause nephrotic syndrome or acute respiratory distress syndrome (ARDS). Although most patients are symptomatic, some patients are normotensive and asymptomatic, particularly when the tumor is nonsecretory or discovered at an early stage.

**B. Laboratory Findings**

Plasma fractionated free metanephrines is the single most sensitive test for secretory pheochromocytomas and paragangliomas. Normal levels rule out pheochromocytoma and paraganglioma with some certainty and the work-up can usually end there. However, misleading elevations in metanephrines or normetanephrines can be caused by factors such as physical or emotional stress, sleep apnea, and MAO inhibitors. Therefore, patients with elevated plasma metanephrines or normetanephrines levels require further evaluation.

Assay of urinary fractionated metanephrines and creatinine effectively confirms most pheochromocytomas that were detected by elevated plasma fractionated metanephrines. A 24-hour urine specimen is usually obtained, although an overnight or shorter collection may be used; patients with pheochromocytomas generally have more than 2.2 mcg of total metanephrine per milligram of creatinine, and more than 135 mcg total catecholamines per gram creatinine. Urinary assay for total metanephrines is about 97% sensitive for detecting functioning pheochromocytomas. Urinary assay for vanillylmandelic acid (VMA) is not usually required.

Some drugs and foods can interfere with certain assays for catecholamines, and stresses can also cause misleading elevations in catecholamine excretion (Table 26–13). About 10% of hypertensive patients have a misleadingly elevated level of one or more tests.

Serum chromogranin A is elevated in 90% of patients with pheochromocytoma and the levels correlate with tumor size, being higher in patients with metastatic disease. Serum chromogranin A levels can be misleadingly elevated in patients with azotemia or hypergastrinemia, and in those treated with corticosteroids or proton pump inhibitors. Serum may also be assayed for neuron-specific enolase; high levels implicate a malignant pheochromocytoma, while normal levels are nonspecific.
pheochromocytoma. A CT scan of the abdomen is performed, with thin sections through the adrenals. A noncontrast CT should be followed by a CT scan using nonionic contrast, which reduces the risk of catecholamine release from a pheochromocytoma and a hypertensive crisis. Glucagon should not be used during scanning, since it can provoke hypertensive crisis; similarly, intravenous contrast can precipitate hypertensive crisis, particularly in patients whose hypertension is uncontrolled.

MRI scanning has the advantage of not requiring intravenous contrast dye; its lack of radiation makes it the imaging of choice during pregnancy and childhood. Both CT and MRI scanning have a sensitivity of about 90% for adrenal pheochromocytoma and a sensitivity of 95% for adrenal tumors over 0.5 cm in diameter. However, both CT and MRI are less sensitive for detecting recurrent tumors, metastases, and extra-adrenal paragangliomas. If no adrenal tumor is found, the scan is extended to include the entire abdomen, pelvis, and chest.

ACTH, adrenocorticotropic hormone; ARDS, acute respiratory distress syndrome; CVA, cerebrovascular accident; PTHrP, parathyroid hormone–related protein; TIA, transient ischemic attack; VIP, vasoactive intestinal peptide.

Pharmacologic provocative and suppressive tests that evaluate the rise or fall in blood pressure are usually not required or recommended. Hyperglycemia is present in about 35% of patients but is usually mild. Leukocytosis is common. The ESR is sometimes elevated. PRA may be increased by catecholamines.

Genetic testing should ideally be performed on all patients with pheochromocytoma or paraganglioma. Testing for VHL, *ret* protooncogene, and SDHB/SDHD mutations is advisable. Family members may then be screened for the specific gene mutation.

**C. Imaging**

**1. CT and MRI scanning**—Imaging should not usually replace biochemical testing, since incidental adrenal adenomas are common (2–4% of scans) and can be misleading. When a pheochromocytoma is suspected because of biochemical testing or a genetic condition predisposing to pheochromocytoma, a CT scan of the abdomen is performed, with thin sections through the adrenals. A noncontrast CT should be followed by a CT scan using nonionic contrast, which reduces the risk of catecholamine release from a pheochromocytoma and a hypertensive crisis. Glucagon should not be used during scanning, since it can provoke hypertensive crisis; similarly, intravenous contrast can precipitate hypertensive crisis, particularly in patients whose hypertension is uncontrolled.

MRI scanning has the advantage of not requiring intravenous contrast dye; its lack of radiation makes it the imaging of choice during pregnancy and childhood. Both CT and MRI scanning have a sensitivity of about 90% for adrenal pheochromocytoma and a sensitivity of 95% for adrenal tumors over 0.5 cm in diameter. However, both CT and MRI are less sensitive for detecting recurrent tumors, metastases, and extra-adrenal paragangliomas. If no adrenal tumor is found, the scan is extended to include the entire abdomen, pelvis, and chest.

1Increases catecholamine excretion.
2May cause confounding peaks on HPLC chromatograms.
3Decreases catecholamine excretion.

2. Nuclear imaging—A whole-body 123I-meta-iodobenzylguanidine (123I-MIBG) scan can localize tumors with a sensitivity of 94% and a specificity of 92%. It is less sensitive for MEN 2A- or MEN 2B-related pheochromocytomas and for metastases. Preoperative 123I-MIBG scanning is not usually required to confirm that a unilateral adrenal mass is a pheochromocytoma in a patient with classic clinical and biochemical presentation. Preoperative whole-body 123I-MIBG scanning can be useful when the CT scan cannot locate a suspected pheochromocytoma, making a parangangioma more likely; it can also be useful when the CT scan is ambiguous for pheochromocytoma. It is prudent to perform a whole-body 123I-MIBG scan about 3 months postoperatively to determine if metastatic or recurrent tumor is present. Drugs that reduce 123I-MIBG uptake should be avoided, including tricyclic antidepressants and cyclobenzaprine (6 weeks), amphetamines, nasal decongestants, phenoxyazines, haloperidol, diet pills, labetalol, and cocaine (2 weeks).

Somatostatin receptor imaging using 111In-labeled octreotide is only 25% sensitive for detecting an adrenal pheochromocytoma. However, 111In-labeled octreotide is quite sensitive for detecting extra-adrenal pheochromocytomas (parangangiomas) and metastatic pheochromocytomas, sometimes locating tumors that were missed by 123I-MIBG scanning.

PET scanning usually detects tumors using 18F-labeled deoxyglucose (18FDG-PET) or 18F-labeled dopamine (18FD-A-PET), and may demonstrate tumors that are not visible on 123I-MIBG scanning. Combining PET scan with noncontrast CT produces a PET/CT fusion scan with exceptional sensitivity.

Differential Diagnosis

Certain conditions mimic pheochromocytoma: thyrotoxicosis, essential hypertension, myocarditis, glomerulonephritis or other renal lesions, eclampsia, and psychoneurosis (anxiety attack). Toxemia of pregnancy is associated with hypertension and increased catecholamine production.

Conditions that have manifestations similar to those of pheochromocytoma include the following: essential labile hypertension, renal hypertension, anxiety attacks, thyrotoxicosis, toxemia of pregnancy, acute intermittent porphyria, hypogonadal vascular instability (hot flushes), cocaine or amphetamine use, and clonidine withdrawal. Patients taking nonselective MAO inhibitor antidepressants can have hypertensive crisis after eating foods that contain tyramine (e.g., fermented cheeses, aged wines, certain beers, fava beans, vegemite, marmite). Patients with erythromelalgia can have hypertensive crises; their episodic painful flushing and leg swelling are relieved by cold, distinguishing this condition from pheochromocytoma. Pheochromocytomas can cause chest pain and ECG changes that mimic acute cardiac ischemia. Renal artery stenosis can cause severe hypertension and may coexist with pheochromocytoma.

False-positive testing for catecholamines and metabolites occurs in about 10% of hypertensives, but levels are usually < 50% above normal and typically normalize with repeat testing.

Complications

All of the complications of severe hypertension may be encountered. In addition, a catecholamine-induced myocardopathy may develop. Severe heart failure and cardiovascular collapse may develop in patients during a paroxysm. Sudden death may occur due to cardiac arrhythmia. ARDS has been reported. Hypertensive crises with sudden blindness or cerebrovascular accidents are not uncommon. Paroxysms may be spontaneous or precipitated by sudden movement, exertion, manipulation, vaginal delivery, emotional stress, trauma, or surgical removal of the tumor. Decongestant medications, fluoxetine, and other selective serotonin reuptake inhibitors may induce hypertensive paroxysms and death. Occasionally, the initial manifestation of pheochromocytoma may be hypotension or even shock.

After removal of the tumor, a state of severe hypotension and shock (resistant to epinephrine and norepinephrine) may ensue with precipitation of kidney disease or myocardial infarction. Hypotension and shock may occur from spontaneous infarction or hemorrhage of the tumor. On rare occasions, a patient dies as a result of the complications of diagnostic tests or during surgery. During surgery, pheochromocytoma cells may be seeded within the peritoneum, resulting in multifocal recurrent tumors.

Medical Treatment

Patients must receive adequate treatment for hypertension and tachyarrhythmias prior to surgery for pheochromocytoma/parangangioma. Patients are advised...
to use a portable sphygomanometer and measure their blood pressures daily and immediately during paroxysms. Some patients with pheochromocytoma or paraganglioma are not hypertensive and do not require preoperative antihypertensive management.

**α-Blockers** are typically administered preparatory to surgery. Phenoxybenzamine is a long-acting nonselective α-blocker with a half-life of 24 hours; it is given initially in a dosage of 10 mg orally every 12 hours, increasing gradually by about 10 mg/d about 3 days until hypertension is controlled. Maintenance doses range from 10 mg/d to 120 mg/d. Selective α₁-blockers may be used: doxazosin (half-life 22 hours), terazosin (half-life 12 hours), or prazosin (half-life 3 hours). Patients given preoperative phenoxybenzamine experience less intraoperative hypertension than patients given preoperative selective α₁-blockers. Optimal α-blockade is achieved when supine arterial pressure is below 140/90 mm Hg or as low as possible for the patient to have a standing arterial pressure above 80/45 mm Hg.

**Calcium channel blockers** (nifedipine ER or nicardipine ER) are very effective and may be used with or without α-blockers. They are superior to phenoxybenzamine for long-term use, since they cause less fatigue, nasal congestion, and orthostatic hypotension. For acute hypertensive crisis (systolic blood pressure > 170 mm Hg) a nifedipine 10-mg capsule may be chewed and swallowed. Nifedipine is quite successful for treating acute hypertension in patients with pheochromocytoma/paraganglioma, even at home; it is reasonably safe as long as the blood pressure is monitored.

**β-Blockers** (eg, metoprolol XL) are often required after institution of α-blockade or calcium channel blockade. The use of a β-blocker as initial antihypertensive therapy has resulted in an “unopposed alpha” that causes paradoxical worsening of hypertension. Labetalol has combined α- and β-blocking activity and is an effective agent but can cause paradoxical hypertension if used as the initial antihypertensive agent. Labetalol can also interfere with catecholamine determinations in some laboratories and reduce the tumor’s uptake of radioisotopes, so that it must be discontinued for at least 4–7 days before diagnostic scanning with ¹²³I-MIBG or ¹⁸F-PET or ¹³¹I-MIBG therapy.

### Surgical Treatment

Surgical removal of pheochromocytomas or abdominal paragangliomas is the treatment of choice. For surgery, a team approach—endocrinologist, anesthesiologist, and surgeon—is critically important. Laparoscopic surgery is preferred, but large and invasive tumors require open laparotomy. Patients with small familial or bilateral pheochromocytomas may undergo selective resection of the tumors, sparing the adrenal cortex; however, there is a recurrence rate of 10% over 10 years.

Prior to surgery, blood pressure control should be maintained for a minimum of 4–7 days or until optimal cardiac status is established. The ECG should be monitored until it becomes stable. (It may take a week or even months to correct ECG changes in patients with catecholamine myocarditis, and it may be prudent to defer surgery until then in such cases.) Patients must be very closely monitored during surgery to promptly detect sudden changes in blood pressure or cardiac arrhythmias.

Intraoperative severe hypertension is managed with continuous intravenous nicardipine (a short-acting calcium channel blocker), 2–6 mcg/kg/min, or nitroprusside, 0.5–10 mcg/kg/min. Prolonged nitroprusside administration can cause cyanide toxicity. Tachyarrhythmia is treated with intravenous atenolol (1 mg boluses), esmolol, or lidocaine.

Autotransfusion of 1–2 units of blood at 12 hours preoperatively plus generous intraoperative volume replacement reduces the risk of postresection hypotension caused by desensitization of the vascular α₁-receptors. Shock may therefore occur following removal of the pheochromocytoma. It is treated with intravenous saline or colloid and high doses of intravenous norepinephrine. Intravenous 5% dextrose is infused postoperatively to prevent hypoglycemia.

#### Managing Metastatic Pheochromocytoma & Paraganglioma

Surgical histopathology for pheochromocytoma or paraganglioma cannot reliably determine whether a tumor is malignant. Therefore, all pheochromocytomas and paragangliomas must be approached as possibly malignant. Even if no metastases are visible at the time of surgery, they may become apparent years later. So all patients require lifetime follow-up. Therefore, it is essential to recheck plasma fractionated metanephrines levels postoperatively, at least 2–4 weeks after surgery and when the patient has minimal residual pain. It is also prudent to perform a whole-body ¹²³I-MIBG scan about 3 months postoperatively, since previously undetected metastases may become visible. Thereafter, blood pressure and symptoms must be rechecked regularly for life; plasma fractionated metanephrines are also rechecked regularly, at least every 6 months for 5 years, then once yearly for life and immediately if hypertension or symptoms recur or if metastases become evident. Since some metastases are indolent, it is important to tailor treatment to each individual according to their tumor’s aggressiveness. Most surgeons resect the main tumor and larger metastases (debulking). Indolent metastases may be kept under close surveillance. Patients with osteolytic bone metastases may be treated with external beam radiation therapy, which is often helpful in relieving pain and stabilizing local osseous disease. Intravenous zoledronic acid may also be administered to patients with osteolytic bone metastases. Various chemotherapy regimens have been used, but there have been no controlled clinical trials to prove the effectiveness of one regimen over another or whether any regimen actually improves overall survival. The most common chemotherapy regimen combines cyclophosphamide, vincristine, and dacarbazine in cycles that are repeated every 3 weeks. About one-third of patients experience some degree of temporary remission. Another chemotherapy regimen uses temozolomide, 250 mg/d orally for 5 days, repeating the cycle every 28 days. Sunitinib, a tyrosine kinase inhibitor, can also produce remissions, given in doses of 50 mg/d for 4 weeks on and then 2 weeks off; alternatively, a dose of 37.5 mg/d can be
given continuously. Each chemotherapy regimen has toxicities.

About 60% of patients with metastatic pheochromocytoma or paraganglioma have tumors with sufficient uptake of $^{123}$I-MIBG on diagnostic scanning to allow for therapy with high-activity $^{131}$I-MIBG. Activities of 125–500 mCi are infused, with many centers administering repeated infusions of 2 mCi/kg to cumulative activities of at least 500–800 mCi. Radioisotope therapy can suppress the bone marrow temporarily. Myelodysplastic syndrome and leukemia can develop several years after $^{131}$I-MIBG therapy, with the risk proportional to the cumulative amount of isotope. ARDS and multisystem failure can occur rarely after doses of 131I-MIBG.

phosphamide, vincristine, and dacarbazine) or with high may be treated with combination chemotherapy (eg, cyclo-
hydration must be ensured. Metastatic pheochromocytomas causes central nervous system side effects and crystalluria; metyrosine treatment proteinuria.

channel blockers has reduced surgical mortality to
erative blood pressure control with

Formerly, the surgical mortality was as high as 30%, but

Patients with metastatic pheochromocytoma and para-
ganglioma have an extremely variable prognosis. Patients
with a heavy and progressive tumor burden and distant metastases have a worse prognosis; patients with multiple pulmonary metastases have limited survival. Patients harboring SDHB germine mutations often have more aggressive tumors. Those with metastases limited to the abdomen or bone tend to have a better prognosis. Patients who receive surgery and chemotherapy have a median survival of about 44%. Patients undergoing surgery and high-dose $^{131}$I-MIBG therapy have been reported to have a 5-year survival rate of 75%. It is important to note that some patients have an indolent malignancy and prolonged survivals of up to 30 years have been reported with no treatment.

## Prognosis

The malignancy of a pheochromocytoma or sympathetic paraganglioma cannot be determined by its size or histologic examination. A tumor is considered malignant if metastases are present; this may take many years to become clinically evident. Therefore, lifetime surveillance is required. Malignancy is more likely for larger tumors and for sympathetic paragangliomas. The prognosis is good for patients with pheochromocytomas that are resected before causing cardiovascular damage. Hypertension usually resolves after successful surgery but may persist or return in 25% of patients despite successful surgery. Although this may be essential hypertension, biochemical reevaluation is then required, looking for a second or metastatic pheochromocytoma.

Formerly, the surgical mortality was as high as 30%, but the development of laparoscopic surgical techniques, improved anesthesia, intraoperative monitoring, and preoperative blood pressure control with $\alpha$-blockers or calcium channel blockers has reduced surgical mortality to $<3\%$.

Patients with metastatic pheochromocytoma and paraganglioma have an extremely variable prognosis. Patients with a heavy and progressive tumor burden and distant metastases have a worse prognosis; patients with multiple pulmonary metastases have limited survival. Patients harboring SDHB germine mutations often have more aggressive tumors. Those with metastases limited to the abdomen or bone tend to have a better prognosis. Patients who receive surgery and chemotherapy have a median survival of about 44%. Patients undergoing surgery and high-dose $^{131}$I-MIBG therapy have been reported to have a 5-year survival rate of 75%. It is important to note that some patients have an indolent malignancy and prolonged survivals of up to 30 years have been reported with no treatment.

## ISLET CELL TUMORS

### ESSENTIALS OF DIAGNOSIS

- Half the tumors are nonsecretory; weight loss, abdominal pain, or jaundice may be presenting signs.
- Secretory tumors cause a variety of manifestations depending on the hormones secreted.

### General Considerations

The pancreatic islets are composed of several types of cells, each with distinct chemical and microscopic features: the A cells (20%) secrete glucagon, the B cells (70%) secrete insulin, and the D cells (5%) secrete somatostatin or gastrin. F cells secrete “pancreatic polypeptide.”

Pancreatic neuroendocrine tumors constitute $<5\%$ of all pancreatic tumors. Pancreatic neuroendocrine tumors are rare, with an incidence of about 10 per million yearly. About 40% are functional, producing hormones that are tumor markers, which are important for diagnosis and follow-up. Although most pancreatic and duodenal neuroendocrine tumors arise spontaneously, they may occur as part four different inherited disorders: MEN 1,
von Hippel-Lindau disease (VHL), neurofibromatosis 1 (NF-1) and the rare tuberous sclerosis complex (TSC).

**Insulinomas** are usually benign (about 90%) and secrete excessive amounts of insulin that causes hypoglycemia. Insulinomas also produce proinsulin and C-peptide. Insulinomas are solitary in 95% of sporadic cases but are multiple in about 90% of cases arising in MEN 1. (See Chapter 27.)

**Gastrinomas** secrete excessive quantities of the hormone gastrin (as well as “big” gastrin), which stimulates the stomach to hypersecrete acid, thereby causing hyperplastic gastric rugae and peptic ulceration (Zollinger–Ellison syndrome). About 50% of gastrinomas are malignant and metastasize to the liver. Gastrinomas are typically found in the duodenum (49%), pancreas (24%), or lymph nodes (11%). Sporadic Zollinger–Ellison syndrome is rarely suspected at the onset of symptoms; typically, there is a 5-year delay in diagnosis. About 22% of patients have MEN 1. In patients with MEN 1, gastrinomas usually present at a younger age; hyperparathyroidism may occur from 14 years preceding the Zollinger–Ellison diagnosis to 38 years afterward.

**Glucagonomas** are usually malignant; liver metastases are ordinarily present by the time of diagnosis. They usually secrete other hormones besides glucagon, often gastric.

**Somatostatinomas** are very rare and are associated with weight loss, diabetes mellitus, malabsorption, and hypochlorhydria.

**VIPomas** are rare pancreatic neuroendocrine tumors that produce vasoactive intestinal polypeptide (VIP), a substance that causes profuse watery diarrhea and profound hypokalemia (Verner-Morrison syndrome).

**Nonfunctional** pancreatic neuroendocrine tumors produce no significant hormones and usually grow to large size prior to detection. They typically present with symptoms caused by mass effect.

**Carcinoid** pancreatic neuroendocrine tumors are typically indolent but usually metastasize to local and distant sites, particularly to other endocrine organs.

### Clinical Findings

#### A. Symptoms and Signs

Presenting symptoms and signs of gastrinomas include abdominal pain (75%), diarrhea (73%), heartburn (44%), bleeding (25%), or weight loss (17%). Endoscopy usually discovers prominent gastric folds (94%).

The 5-, 10-, and 20-year survival rates with MEN 1 are 94%, 75%, and 58%, respectively, while the survival rates for sporadic Zollinger–Ellison syndrome are 62%, 50%, and 31%, respectively. (See Chapter 15.)

Initial symptoms of glucagonoma often include weight loss, diarrhea, nausea, peptic ulcer, or necrotic migratory erythema. About 35% of patients ultimately develop diabetes mellitus. The median survival is 34 months after diagnosis.

Carcinoid pancreatic neuroendocrine tumors secrete serotonin and can produce an atypical carcinoid syndrome manifested by pain, diarrhea, and weight loss; skin flushing occurs in 39% of patients. Islet cell tumors can secrete ectopic hormones in addition to native hormones, often in combinations that produce various clinical syndromes. They may secrete ACTH and cause Cushing syndrome.

#### B. Imaging

Localizations of noninsulinoma pancreatic islet cell tumors and their metastases are best done with somatostatin receptor scintigraphy (SRS); SRS detects about 75% of noninsulinomas. CT and MRI are also useful. Insulinomas can usually be located preoperatively by endoscopic ultrasonography. For insulinomas, preoperative localization studies are less successful and have the following sensitivities: ultrasonography 25%, CT 25%, endoscopic ultrasonography 27%, transhepatic portal vein sampling 40%, arteriography 45%, intraoperative palpation 55%, and intraoperative pancreatic ultrasound 75%. Nearly all insulinomas can be successfully located at surgery by intraoperative palpation and ultrasonogram. An abdominal CT scan is usually obtained, but extensive preoperative localization procedures, especially with invasive methods, are not required. Tumors may be located in the pancreatic head or neck (57%), body (15%), or tail (19%) or in the duodenum (9%).

#### Treatment

Direct resection of the tumor (or tumors), which often spread locally, is the primary form of therapy for all types of islet cell neoplasms. In Zollinger–Ellison syndrome, gastrinomas are most commonly found in the duodenum but also in the pancreas. Gastric hyperacidity in Zollinger–Ellison syndrome is treated with a proton pump inhibitor at quadruple the usual doses. Proton pump inhibitors increase serum gastrin, which is the tumor marker for gastrinomas; hypercalcemia also stimulates gastrin release.

Insulinomas must be localized with biphasic thin section helical CT and endoscopic ultrasound. Surgery must be guided, either by preoperative endoscopic ultrasound tattooing or by laparoscopic intraoperative ultrasound. Surgery is usually successful for sporadic insulinomas. However, in MEN 1, insulinomas are rarely cured by surgery, with the exception of total pancreatectomy. The hypoglycemia caused by insulinomas may be counteracted by verapamil or diazoxide.

Octreotide LAR is useful in the therapy of islet cell tumors with the exception of insulinoma; subcutaneous injections of 20–30 mg are required every 4 weeks. Treatment with octreotide LAR improves the symptoms caused by excessive VIP but does not halt tumor growth. Selective radioembolization of hepatic metastases can be accomplished with the use of yttrium-90(Y)-labeled resin or glass microspheres. The use of streptozocin, doxorubicin, and asparaginase, especially for malignant insulinoma, has produced some encouraging results, though these drugs are quite toxic. Combined chemotherapy with 5-fluoracil, dacarbazine, and epirubicin has also been effective (see Table 39–12).

The prognosis in these neoplasms is variable. The surgical complication rate is about 40%, with patients commonly developing fistulas and infections. Extensive pancreatic resection may cause diabetes mellitus. The overall 5-year survival is higher with functional tumors (77%) than with
MALE HYPOGONADISM

ESSENTIALS OF DIAGNOSIS

- Diminished libido and erections.
- Fatigue, depression, reduced exercise endurance.
- Decreased growth of body hair.
- Testes may be small or normal in size.
- Serum testosterone or free testosterone is decreased.
- Serum gonadotropins (LH and FSH) are decreased or normal in hypogonadotropic hypogonadism; they are increased in testicular failure (hypergonadotropic hypogonadism).

General Considerations

Male hypogonadism is caused by deficient testosterone secretion by the testes. It may be classified according to whether it is due to (1) insufficient gonadotropin secretion by the pituitary (hypogonadotropic); (2) pathology in the testes themselves (hypergonadotropic); or (3) both (Table 26–14). Partial male hypogonadism may be difficult to distinguish from the physiologic reduction in serum testosterone seen in normal aging, obesity, and illness.

Etiology

A. Hypogonadotropic Hypogonadism (Low Testosterone with Normal or Low LH)

A deficiency in FSH and LH may be isolated or associated with other pituitary hormonal abnormalities. (See

Table 26–14. Causes of male hypogonadism.

Hypopituitarism.) Hypogonadotropic hypogonadism can be primary, with a failure to enter puberty by age 14; the differential diagnosis is isolated hypogonadotropic hypogonadism, hypopituitarism, or simply delayed puberty (constitutional delay of growth and puberty). Hypogonadotropic hypogonadism may also be acquired. Causes of acquired hypogonadotropic hypogonadism include pituitary or hypothalamic tumors, granulomatous diseases, lymphocytic hypophysitis, or hemochromatosis. Other causes of acquired hypogonadotropic hypogonadism include Cushing syndrome, adrenal insufficiency, and thyroid hormone excess or deficiency. Genetic conditions (eg, Kallman syndrome or PROKR2 mutations) account for about 40% of cases of acquired hypogonadotropic hypogonadism that is isolated, severe (serum testosterone < 150 ng/dL), and apparently idiopathic.

The main causes of male partial acquired hypogonadotropic hypogonadism (serum testosterone 150–300 ng/dL) are functional and include obesity, poor health, or normal aging. Spermatogenesis is usually preserved. After age 40, serum total testosterone declines variably by an average of 1–2% per year; serum free testosterone levels decline even faster, since sex hormone binding globulin increases with age. After age 70 years, 28% of men have low serum total testosterone and 68% have low serum free testosterone levels, compared with the levels found in young men. Serum levels of free testosterone are lower in men aged 40–70 compared with younger men, without any increase in serum LH. After age 70, LH levels tend to rise, indicating a contribution of primary gonadal dysfunction with advanced age.

nonfunctional ones (55%) and higher with benign tumors (91%) than with malignant ones (55%).
There is considerable clinical and laboratory overlap between patients with partial hypogonadotropic hypogonadism and those with normal aging, obesity, or illness. A multicenter European study concluded that the diagnosis of testosterone deficiency in older men should include a serum testosterone < 320 ng/mL and at least three of the following six symptoms: erectile dysfunction, poor morning erection, low libido, depression, fatigue, and inability to perform vigorous activity. Such men are most likely to benefit from testosterone replacement.

**B. Hypergonadotropic Hypogonadism (Testicular Failure with High LH)**

A failure in testicular secretion of testosterone causes a rise in LH. If testicular Sertoli cell function is deficient, FSH will be elevated. Conditions that can cause testicular failure include viral infection (eg, mumps), irradiation, cancer chemotheraphy or radioisotope therapy, autoimmunity, myotonic dystrophy, uremia, XY gonadal dysgenesis, partial 17-ketosteroid reductase deficiency, Klinefelter syndrome, and male climacteric. In men who have had a unilateral orchietomy for cancer, the remaining testicle can fail even in the absence of radiation or chemotheraphy. Male hypogonadism can also be caused by a congenital partial deficiency in the steroidogenic enzyme CYP17 (17-hydroxylase). CYP17 may be deliberately inhibited by abiraterone acetate (Zytiga), a drug for prostate cancer. CYP17 inhibition also causes adrenocortical insufficiency, hypertension, and hypokalemia.

**Klinefelter syndrome** (47,XXY and its variants) is the most common chromosomal abnormality among males, with an incidence of about 1:500. It is caused by the expression of an abnormal karyotype, classically 47,XXY. Other forms are common, eg, 46,XY/47,XXY mosaicism, 48,XXYY, 48,XXXY, or 46,XX males.

The manifestations of Klinefelter syndrome are variable. Testes feel normal during childhood, but during adolescence they usually become firm, fibrotic, and small, and the patient may have a palpable mass. Although puberty occurs at the normal time, the degree of virilization is variable. About 85% of patients have some gynecomastia at puberty. Other causes of gynecomastia (Table 26–15) must be excluded. Other common findings include tall stature and abnormal body proportions that are unusual for hypogonadism. Other abnormalities such as clinodactyly or synostosis may also occur.

The diagnosis of Klinefelter syndrome is confirmed by karyotyping or by determining the presence of RNA for X-inactive-specific transcriptase (XIST) in peripheral blood leukocytes by polymerase chain reaction.

On semen analysis, most men (about 95%) with classic Klinefelter syndrome have azoospermia, although some sperm production is often present in their early teens. Men with 46,XY/47,XXY mosaicism may have spontaneous fertility. Also, testicular biopsy reveals sperm in up to 50% of affected patients, allowing some of them to be fertile with the use of in vitro fertilization using intracytoplasmic sperm injection (ICSI).

**XY gonadal dysgenesis** describes several conditions that result in the failure of the testes to develop normally.

</table>
SRY is a gene on the Y chromosome that initiates male sexual development. Mutations in SRY result in testicular dysgenesis. Affected individuals lack testosterone, which results in sex reversal: female external genitalia with a blind vaginal pouch, no uterus, and intra-abdominal dysgenetic gonads. Affected individuals are raised as girls and appear normal until their lack of pubertal development and amenorrhea leads to the diagnosis. Intra-abdominal rudimentary testes have an increased risk of developing a malignancy and are usually resected. Patients are considered women and receive estrogen replacement therapy.

**C. Androgen Insensitivity**

Partial resistance to testosterone is a rare condition in which phenotypic males have variable degrees of apparent hypogonadism, hypospadias, cryptorchism, and gynecomastia. Serum testosterone levels are normal.

**Clinical Findings**

**A. Symptoms and Signs**

Hypogonadism that is congenital or acquired during childhood presents as delayed puberty. Men with acquired hypogonadism have variable manifestations. Most men experience decreased libido. Others complain of erectile dysfunction, poor morning erection, or hot sweats. Men often have depression, fatigue, or decreased ability to perform vigorous physical activity. The presenting complaint may also be infertility, gynecomastia, headache, fracture, or other symptoms related to the cause or result of the hypogonadism. The patient’s history often gives a clue to the cause (Table 26–14).

Physical signs associated with hypogonadism may include decreased body, axillary, beard, or pubic hair; such diminished sexual hair growth is not reliably present except after years of severe hypogonadism. Men in whom hypogonadism develops tend to lose muscle mass and gain weight due to an increase in subcutaneous fat. Examination should include measurements of arm span and height. Testicular size should be assessed with an orchidometer (normal volume is about 10–25 mL; normal length is usually over 6 cm). Testicular size may decrease but usually remains within the normal range in men with postpubertal hypogonadotropic hypogonadism, but it may be diminished with testicular injury or Klinefelter syndrome. The testes must also be carefully palpated for masses, since Leydig cell tumors may secrete estrogen and present with hypogonadism. The testicles must be carefully examined for evidence of trauma, infiltrative lesions (eg, lymphoma), or ongoing infection (eg, leprosy, tuberculosis).

**B. Laboratory Findings**

The evaluation for hypogonadism begins with a morning serum testosterone or free testosterone measurement (or both) using a reliable assay. Most radioimmunoassays and ELISAs for testosterone are inaccurate when serum testosterone levels are < 300 ng/dL. More accurate testosterone assays rely on extraction and chromatography, followed by mass spectrometry or immunoassay. Serum testosterone levels are considered low if they are confirmed to be < 320 ng/dL (11 nmol/L). Free testosterone is best measured by calculation, using accurate assays for testosterone and sex hormone binding globulin. Serum free testosterone levels are considered low if they are confirmed to be < 64 pg/mL (220 pmol/L).

Normal ranges for serum testosterone have been derived from nonfasting morning blood specimens, which tend to be the highest of the day. Later in the day, serum testosterone levels can be 25–50% lower. Therefore, a serum testosterone drawn fasting or late in the day may be misleadingly below the “normal range.” Serum testosterone levels in men are highest at age 20–30 years and slightly lower at age 30–40 years; testosterone falls gradually but progressively after age 40 years. Testing for serum free testosterone is especially important for detecting hypogonadism in elderly men, who generally have high levels of sex hormone binding globulin. A low serum testosterone should be verified with a repeat assay and further evaluated with serum LH and FSH levels. LH and FSH tend to be high in patients with hypergonadotropic hypogonadism but low or inappropriately normal in men with hypogonadotropic hypogonadism or normal aging. Patients with low gonadotropins may be further evaluated for other pituitary abnormalities, including hyperprolactinemia.

Testosterone stimulates erythropoiesis in men, causing the normal red blood count range to be higher in men than in women; mild anemia is common in men with hypogonadism, with red blood counts below the normal male range. For men with long-standing male hypogonadism, bone densitometry is recommended. Men with severe osteoporosis may require treatment with bisphosphonates and vitamin D, in addition to testosterone replacement therapy. (See Osteoporosis section.)

1. **Hypogonadotropic hypogonadism**—A serum PRL determination is obtained but may be elevated for many reasons (see Table 26–2). Men with gynecomastia may be screened for partial 17-ketosteroid reductase deficiency with serum determinations for androstenedione and estrone, which are elevated in this condition. X-linked congenital adrenal hyperplasia is a rare condition in which a DAX-1 gene mutation causes hypogonadotropic hypogonadism and azoospermia, which usually presents in adolescence; the associated primary adrenal insufficiently usually presents in childhood, but it may remain undiagnosed into adulthood. The serum estradiol level may be elevated in patients with cirrhosis and in rare cases of estrogen-secreting tumors (testicular Leydig cell tumor or adrenal carcinoma). Men with no discernible definite cause for hypogonadotropic hypogonadism should be screened for hemochromatosis and have an MRI of the pituitary and hypothalamic region to look for a tumor or other lesion. (See Hypopituitarism.)

2. **Hypergonadotropic hypogonadism**—Men with hypergonadotropic hypogonadism have low serum testosterone levels with a compensatory increase in FSH and LH. Klinefelter syndrome can be confirmed by karyotyping or by measurement of leukocyte XIST. Testicular biopsy is usually reserved for younger patients in whom the reason for primary hypogonadism is unclear.
Testosterone replacement is reasonable for boys who have not begun puberty by age 14. It is beneficial to most men with hypogonadotropic hypogonadism or severe hypogonadotropic hypogonadism. Men with symptoms of hypogonadism (see above) and a repeatedly low serum testosterone or free testosterone can also benefit from testosterone replacement. For men with borderline low serum testosterone levels and marginal hypogonadal symptoms, the decision to treat should consider the potential benefits versus risks (see below). Such men may be given a trial of testosterone therapy for several months while monitoring their response.

Testosterone therapy should not be administered to men with active prostate or breast cancer, or erythrocytosis. In men over age 50 years, a digital prostate examination and serum prostate-specific antigen (PSA) level should be done before beginning testosterone therapy. Men with symptoms of prostatic hypertrophy, a palpable prostate nodule, or a PSA > 4 ng/ml (> 3 ng/ml in men of African ancestry) should have a urologic evaluation prior to treatment. Serum PSA should be measured yearly during therapy. Similarly, testosterone therapy is not given to men with untreated sleep apnea or congestive heart failure. In men who have coronary risk factors or are over age 65, special attention should be given to improving cardiac risk factors (eg, controlling hypertension or hyperlipidemia) and administering low-dose aspirin while receiving testosterone replacement.

Drug interactions can occur. Testosterone should be administered cautiously to men receiving coumadin, since the combination can increase the INR and risk of bleeding. Similarly, testosterone therapy can increase serum levels of cyclosporine, tacrolimus, and tolvaptan. Testosterone can predispose to hypoglycemia in diabetic men receiving insulin or oral hypoglycemic agents, so close monitoring of blood sugars is advisable during initiation of testosterone therapy.

Oral androgen therapy with methyltestosterone is not advisable due to the potential for causing liver tumors, peliosis hepatis, and cholestatic jaundice (see below).

### A. Formulations of Testosterone Replacement Therapy

1. **Topical testosterone**—Testosterone is best administered topically. Topical administration yields more stable serum testosterone levels than intramuscular administration. Topical testosterone is usually applied once daily in the morning after showering. Topical testosterone should not be applied to the breast or genitals. **Androgel 1%** gel is available in 2.5-g packets (25 mg testosterone) and 5-g packets (50 mg testosterone) and in a pump that dispenses 12.5 mg testosterone per pump actuation; the recommended dose is 50–100 mg applied daily to the shoulders. **AndroGel 1.6%** gel is available in a pump that dispenses 20.25 mg testosterone per pump actuation; the recommended dose is 40.5–81 mg daily. **Testim** 1% gel is available in 5-g tubes (50 mg testosterone); the recommended dose is 50–100 mg applied daily. **Fortesta 2%** gel is available in a pump that dispenses 10 mg testosterone per pump actuation; the recommended dose is 40–70 mg daily. **Testogel** is distributed in 5-g sachets (50 mg testosterone); this brand is not available in the United States. **Testim, Fortesta, and Testogel** may be applied to both shoulders, upper arms, or abdomen. **Axiron 2%** solution is available in a pump that dispenses 30 mg per actuation; the recommended dose is 30–60 mg applied to each axilla daily.

The skin serves as a reservoir that slowly releases about 10% of the testosterone into the blood; serum testosterone levels reach a steady state in 1–3 days. The serum testosterone level should be determined about 14 days after starting therapy; if the level remains below normal or the clinical response is inadequate, the daily dose may be increased to 1.5 to 2 times the initial dose. After the application of topical testosterone, the hands should be washed. The application site should be allowed to dry for 5–10 minutes before dressing. Before close contact with women or children, a shirt must be worn or the areas of application washed with soap and water to prevent transfer of testosterone to them.

2. **Transdermal testosterone**—Testosterone transdermal systems (skin patches) are available in two formulations for application to nongenital skin. **Testoderm II, 5 mg/d leaves a sticky residue but causes little skin irritation. Androderm (2 or 4 mg/24 h) patches may be applied at bedtime in doses of 4–8 mg; it adheres more tightly to the skin but may cause more skin irritation. Both produce reliable serum levels of testosterone that are somewhat lower than those achieved with injections. The patch systems also suffer from being rather inconvenient and expensive.

3. **Parenteral testosterone**—Testosterone cypionate and testosterone enanthate are intramuscular testosterone formulations that are available in solutions containing 200 mg/ml. Their main advantage is low cost. The usual dose is 200 mg every 2 weeks or 300 mg every 3 weeks. The dose and injection intervals are adjusted according to the patient’s response. These preparations are oil-based and are usually given intramuscularly in the gluteal area.

Testosterone undecanoate (Nebido) is a long-lasting depot testosterone formulation that is administered in doses of 1000 mg (4 mL) by slow intramuscular injection. The initial injection is followed by another 1000 mg injection 6 weeks later and maintenance doses of 1000 mg every 3 months. A serum testosterone level is measured before the fourth dose; if the serum testosterone remains low, the dosing interval is shortened to every 10 weeks. It is not available in the United States or Canada.

4. **Buccal testosterone**—Testosterone buccal tablets (Striant) are placed between the upper lip and gingivae. One or two 30-mg tablets are thus retained and changed every 12 hours. They should not be chewed or swallowed.

5. **Oral testosterone**—Oral androgen preparations include methyltestosterone and fluoxymesterone. Another oral preparation is testosterone undecanoate; it is not approved in the United States. These oral preparations can cause liver tumors or peliosis hepatis with long-term use. Cholestatic jaundice occurs in 1–2% of patients but usually remits after the medication is discontinued. Oral androgens are not as effective as topical or parenteral testosterone.
B. Benefits of Testosterone Replacement Therapy

Testosterone therapy usually benefits men with low serum testosterone and at least three manifestations of hypogonadism as noted above. Testosterone therapy can improve overall mood, sense of well-being, sexual desire, and erectile function. It also increases physical vigor and muscle strength as manifested in measurements of leg-press and chest-press strength. Testosterone replacement also improves exercise endurance and stair climbing ability.

C. Risks of Testosterone Replacement Therapy

Testosterone replacement therapy appears to increase the risk of cardiovascular events in men older than age 65 with cardiac risk factors or preexisting angina. This increased risk may be due to the decrease in serum HDL that can occur with testosterone therapy.

Testosterone therapy can aggravate benign prostatic hypertrophy (BPH). However, aggravation of voiding problems is uncommon. In men with BPH, finasteride may be coadministered with testosterone to reduce prostate size. The incidence of prostate cancer does not appear to be increased by testosterone therapy. However, testosterone therapy is contraindicated in the presence of active prostate cancer. Hypogonadal men who have had a prostatectomy for low-grade prostate cancer, and who have remained in complete remission for several years, may have testosterone therapy given cautiously while monitoring sensitive serum PSA levels.

Erythrocytosis develops in some men who are treated with testosterone. Erythrocytosis is more common with intramuscular injections of testosterone enanthate than with transcutaneous testosterone. However, no increase in the incidence of thromboembolic events has been reported.

Testosterone therapy tends to aggravate sleep apnea in older men, likely through central nervous system effects. Surveillance for sleep apnea is recommended during testosterone therapy and a formal evaluation with nocturnal pulse oximetry recording is recommended for all high-risk patients with snoring, obesity, partner’s report of apneic episodes, nocturnal awakening, unrefreshing sleep with daytime fatigue, or hypertension.

Men who are treated with testosterone frequently experience some increase in acne that is usually mild and tolerated; topical antiacne therapy or a reduction in testosterone replacement dosage may be required. Increases in intraocular pressure have occurred during testosterone therapy. During the initiation of testosterone replacement therapy, gynecomastia develops in some men, which usually is mild and tends to resolve spontaneously; switching from testosterone injections to testosterone transdermal gel may help this condition.

Prognosis of Male Hypogonadism

If hypogonadism is due to a pituitary lesion, the prognosis is that of the primary disease (eg, tumor, necrosis). The prognosis for restoration of virility is good if testosterone is given.
Some patients have underlying hypogonadism, including hypogonadotropic hypogonadism. If the testes are not palpable, ultrasound or MRI can be used to locate them. Alternatively, hCG, 1500 units intramuscularly daily for 3 days, causes a significant rise in testosterone if the testes are present. Therapy with hCG results in a testicular descent rate of about 25%. Compared to an incidence of 0.002% in normal males, cryptorchid testes increase the lifetime risk of testicular neoplasia to about 0.06%, and intra-abdominal testes, to 5%. Orchiopexy decreases the risk of neoplasia when performed before 10 years of age. Orchiectomy after puberty is an option for intra-abdominal testes.

**Clinical Findings**

**A. Symptoms and Signs**

The male breasts must be palpated carefully to distinguish true glandular gynecomastia from fatty pseudogynecomastia in which only adipose tissue is felt. The breasts are best examined both seated and supine. Using the thumb and forefinger as pincers, the subareolar tissue is compared to nearby adipose tissue. Fatty gynecomastia is usually diffuse and nontender. Glandular enlargement beneath the areola may be tender. Pubertal gynecomastia is characterized by tender discoid enlargement of breast tissue 2–3 cm in diameter beneath the areola. The following characteristics are worrisome for malignancy: asymmetry; location not immediately below the areola; unusual firmness; or nipple retraction, bleeding, or discharge. Gynecomastia is graded according to severity: I, mild; II, moderate; III, severe.

**B. Laboratory Findings**

Obtain plasma levels of PRL (see Hyperprolactinemia) and the β-subunit of hCG (β-hCG). Detectable levels of β-hCG implicate a testicular tumor (germ cell or Sertoli cell) or other malignancy (usually lung or liver). Detectable low levels of serum β-hCG (<5 mU/mL) may be reported in men with primary hypogonadism and high serum LH levels if the assay for β-hCG cross-reacts with LH. Measurements of serum free testosterone and LH are valuable in the diagnosis of primary or secondary hypogonadism. A low serum free testosterone and high LH are seen in primary hypogonadism. High testosterone levels plus high LH levels characterize partial androgen resistance. Serum estradiol is determined but is usually normal; increased levels may result from testicular tumors, increased β-hCG, liver disease, obesity, adrenal tumors (rare), true hermaphroditism (rare), or gain of function mutations affecting the aromatase gene (rare). Many estrogens and substances with estrogenic activity are not detected by estradiol assays. Serum TSH (sensitive) and FT₄ levels are also determined. A karyotype (for Klinefelter syndrome) is obtained in men with persistent gynecomastia without obvious cause.

Investigation of unclear cases should include a chest radiograph to search for metastatic or bronchogenic carcinoma. Needle biopsy with cytologic examination may be performed on suspicious areas of male breast enlargement (especially when unilateral or asymmetric) to distinguish gynecomastia from tumor or mastitis.

**Treatment**

Pubertal gynecomastia often resolves spontaneously within 1–2 years. Drug-induced gynecomastia resolves after the offending drug is removed. Spironolactone can be stopped, with substitution of a selective aldosterone antagonist such as eplerenone. Patients with painful or persistent gynecomastia may be treated with medical therapy, which is usually continued for 9–12 months. Generally, it is prudent to treat patients for gynecomastia only when it becomes a troubling and continuing problem for them.

---

**GYNECOMASTIA**

**General Considerations**

Gynecomastia refers to a female-appearing male breast. In practice, it is defined as the presence of palpable glandular breast tissue in males. Pubertal gynecomastia develops in about 60% of boys; the swelling usually subsides spontaneously within a year. Gynecomastia is particularly common in teenagers who are very tall or overweight. Gynecomastia develops in about 50% of athletes who abuse androgens and anabolic steroids. It is seen in Klinefelter syndrome, which affects 1:500 men. (See section on Klinefelter syndrome.) Gynecomastia can develop in HIV-infected patients treated with highly active antiretroviral therapy (HAART), especially in men receiving efavirenz or didanosine; breast enlargement resolves spontaneously in 73% of patients within 9 months. Gynecomastia is common among elderly men, particularly when there is associated weight gain. However, it can be the first sign of a serious disorder.

The causes of gynecomastia are multiple and diverse (Table 26–15).
A. Hypothalamic-Pituitary Causes (with Low or Normal FSH)

A genetic deficiency of GnRH and gonadotropins may be isolated or associated with other pituitary deficiencies or diminished olfaction (Kallmann syndrome). Hypothalamic lesions, particularly craniopharyngioma, may be present. Pituitary tumors may be nonsecreting or may secrete PRL or GH. Cushing syndrome may be caused by corticosteroid treatment, a cortisol-secreting adrenal tumor, or an ACTH-secreting pituitary tumor. Hypothyroidism can delay adolescence. Head trauma or encephalitis can cause gonadotropin deficiency. Primary amenorrhea may also be caused by constitutional delay of adolescence, organic illness, vigorous exercise (eg, ballet dancing, running), stressful life events, dieting, or anorexia nervosa; however, these conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation. (See section on Hypopituitarism.)

B. Hyperandrogenism (with Low or Normal FSH)

Excess testosterone may be secreted by adrenal tumors or by adrenal hyperplasia caused by steroidogenic enzyme defects such as P450c21 deficiency (salt-wasting) or P450c11 deficiency (hypertension). Ovarian tumors or polycystic ovaries may also secrete excess testosterone. Androgenic steroids may also cause this syndrome.

C. Ovarian Causes (with High FSH)

Gonadal dysgenesis (Turner syndrome and variants; see below) is a frequent cause of primary amenorrhea. Ovarian failure due to autoimmunity is a common cause. Rare deficiencies in certain ovarian steroidogenic enzymes are causes of primary hypogonadism without virilization: 3β-hydroxysteroid dehydrogenase deficiency (adrenal insufficiency with low serum 17-hydroxyprogesterone) and P450c17 deficiency (hypertension and hypokalemia with high serum 17-hydroxyprogesterone). A whole-body deficiency in P450 aromatase (P450arom) activity produces female hypogonadism associated with polycystic ovaries, tall stature, osteoporosis, and virilization.

D. Pseudohermaphroditism (with High LH)

An enzymatic defect in testosterone synthesis may present as a sexually immature phenotypic girl with primary amenorrhea. Complete androgen resistance (testicular feminization) presents as a phenotypic young woman without sexual hair but with normal breast development and primary amenorrhea. In both cases, the uterus is absent and testes are intra-abdominal or cryptorchid. Intra-abdominal testes are surgically resected. Such patients are treated as normal but infertile, hypogonadal women.

E. Uterine Causes (with Normal FSH)

Congenital absence or malformation of the uterus may be responsible for primary amenorrhea, as may unresponsive or atrophic endometrium. An imperforate hymen is occasionally the reason for the absence of visible menses.
F. Pregnancy (with High hCG)

Pregnancy may be the cause of primary amenorrhea even when the patient denies ever having had sexual intercourse.

▶ Clinical Findings

A. Symptoms and Signs

Patients with primary amenorrhea require a thorough history and physical examination to look for signs of the conditions noted above. Headaches or visual field abnormalities may implicate a hypothalamic or pituitary tumor. Signs of pregnancy may be present. Blood pressure abnormalities, acne, and hirsutism should be noted. Short stature may be seen with an associated GH or thyroid hormone deficiency. Short stature with manifestations of gonadal dysgenesis indicates Turner syndrome (see below). Olfaction testing screens for Kallmann syndrome. Obesity and short stature may be signs of Cushing syndrome. Tall stature may be due to eunuchoidism or gigantism. Hirsutism or virilization suggests excessive testosterone.

An external pelvic examination plus a rectal examination should be performed to assess hymen patency and the presence of a uterus.

B. Laboratory and Radiologic Findings

The initial endocrine evaluation should include serum determinations of FSH, LH, PRL, testosterone, TSH, FT₄, and hCG (pregnancy test). Patients who are virilized or hypertensive require serum electrolyte determinations and further hormonal evaluation. MRI of the hypothalamus and pituitary is used to evaluate teens with primary amenorrhea. Pelvic duplex/color sonography is very useful and low or normal FSH and LH—especially those with high PRL levels. Pelvic duplex/color sonography is very useful. Girls who have a normal uterus and high FSH without the classic features of Turner syndrome may require a karyotype to diagnose X chromosome mosaicism.

▶ Treatment

Treatment of primary amenorrhea is directed at the underlying cause. Girls with permanent hypogonadism are treated with ERT (see below).

SECONDARY AMENORRHEA & MENOPAUSE

Secondary amenorrhea is defined as the absence of menses for 3 consecutive months in women who have passed menarche. Menopause is defined as the terminal episode of naturally occurring menses; it is a retrospective diagnosis, usually made after 6 months of amenorrhea.

▶ Etiology

The causes of secondary amenorrhea include pregnancy, hypothalamic-pituitary causes, hyperandrogenism, uterine causes, premature ovarian failure, and menopause.

A. Pregnancy (High hCG)

Pregnancy is the most common cause for secondary amenorrhea in women of childbearing age. The differential diagnosis includes rare ectopic secretion of hCG by a choriocarcinoma or bronchogenic carcinoma.

B. Hypothalamic-Pituitary Causes (with Low or Normal FSH)

The hypothalamus must release GnRH in a pulsatile manner for the pituitary to secrete gonadotropins. GnRH pulses occurring more than once per hour favor LH secretion, while less frequent pulses favor FSH secretion. In normal ovulatory cycles, GnRH pulses in the follicular phase are rapid and favor LH synthesis and ovulation; ovarian luteal progesterone is then secreted that slows GnRH pulses, causing FSH secretion during the luteal phase. Most women with hypothalamic amenorrhea have a persistently low frequency of GnRH pulses.

Secondary “hypothalamic” amenorrhea may be caused by stressful life events such as school examinations or leaving home. Such women usually have a history of normal sexual development and irregular menses since menarche. Amenorrhea may also be the result of strict dieting, vigorous exercise, organic illness, or anorexia nervosa. Intrathecal infusion of opioids causes amenorrhea in most women. These conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation. Young women in whom the results of evaluation and progestin withdrawal test are normal have noncyclic secretion of gonadotropins resulting in anovulation. Such women typically recover spontaneously but should have regular evaluations and a progestin withdrawal test about every 3 months to detect loss of estrogen effect.

PRL elevation due to any cause (see section on hyperprolactinemia) may cause amenorrhea. Pituitary tumors or other lesions may cause hypopituitarism. Corticosteroid excess of any cause suppresses gonadotropins.

C. Hyperandrogenism (with Low-Normal FSH)

Elevated serum levels of testosterone can cause hirsutism, virilization, and amenorrhea. In PCOS, GnRH pulses are persistently rapid, favoring LH synthesis with excessive androgen secretion; reduced FSH secretion impairs follicular maturation. Progesterone administration can slow the GnRH pulses, thus favoring FSH secretion that induces follicular maturation. Rare causes include adrenal P450c21 deficiency, ovarian or adrenal malignancies, ectopic ACTH secretion by a malignancy, and Cushing disease. Anabolic steroids also cause amenorrhea.

D. Uterine Causes (with Normal FSH)

Infection of the uterus commonly occurs following delivery or D&C but may occur spontaneously. Endometritis
due to tuberculosis or schistosomiasis should be suspected in endemic areas. Endometrial scarring may result, causing amenorrhea (Asherman syndrome). Such women typically continue to have monthly premenstrual symptoms. The vaginal estrogen effect is normal.

E. Early and Premature Menopause (with High FSH)

Early menopause refers to primary ovarian failure that occurs before age 45. It affects approximately 5% of women. About 1% of women experience premature menopause that is defined as ovarian failure before age 40; about 30% of such cases are due to autoimmunity against the ovary. X chromosome mosaicism accounts for 8% of cases of premature menopause. Other causes include surgical bilateral oophorectomy, radiation therapy for pelvic malignancy, and chemotherapy. Women who have undergone hysterectomy are prone to premature ovarian failure even though the ovaries were left intact. Myotonic dystrophy, galactosemia, and mumps oophoritis are additional causes. Early or premature menopause is frequently familial. Ovarian failure is usually irreversible.

F. Normal Menopause (with High FSH)

Normal menopause refers to primary ovarian failure that occurs after age 45. “Climacteric” is defined as the period of natural physiologic decline in ovarian function, generally occurring over about 10 years. By about age 40 years, the remaining ovarian follicles are those that are the least sensitive to gonadotropins. Increasing titers of FSH are required to stimulate estradiol secretion. Estradiol levels may actually rise during early climacteric.

The normal age for menopause in the United States ranges between 48 and 55 years, with an average of about 51.5 years. Serum estradiol levels fall and the remaining estrogen after menopause is estrone, derived mainly from peripheral aromatization of adrenal androstenedione. Such peripheral production of estrone is enhanced by obesity and liver disease. Individual differences in estrone levels partly explain why the symptoms noted above may be minimal in some women but severe in others.

A careful pelvic examination is always required to check for uterine or adnexal enlargement and to obtain a Papanicolaou smear and a vaginal smear for assessment of estrogen effect. Various life stresses, vigorous exercise, and “crash” dieting all predispose to amenorrhea; however, such factors should not be assumed to account for amenorrhea without a complete workup to screen for other causes.

B. Laboratory Findings

Since pregnancy is the most common cause of amenorrhea, women of childbearing age are immediately screened with a serum or urine hCG (pregnancy test). An elevated hCG overwhelmingly indicates pregnancy; false-positive testing may occur very rarely with ectopic hCG secretion (eg, choriocarcinoma or bronchogenic carcinoma). Women without an elevated hCG receive further laboratory evaluation including serum PRL, FSH, LH, and TSH. Hyperprolactinemia or hypopituitarism (without obvious cause; see section on Hypopituitarism) should prompt an MRI study of the pituitary region. Routine testing for kidney and liver function (eg, BUN, serum creatinine, bilirubin, alkaline phosphatase, and alanine aminotransferase) is also performed. A serum testosterone level is obtained in hirsute or virilized women. Patients with manifestations of hypercortisolism receive a 1-mg overnight dexamethasone suppression test for initial screening (see section on Cushing syndrome). Nonpregnant women without any laboratory abnormality may receive a 10-day course of a progestin (eg, medroxyprogesterone acetate, 10 mg/d); absence of withdrawal menses typically indicates a lack of estrogen or a uterine abnormality.

Clinical Findings

A. Symptoms and Signs

Vasomotor instability (hot flushes) is experienced by 80% of women, lasting seconds to many minutes. Hot flushes with drenching sweats may be most severe at night or may be triggered by emotional stress. Women may also experience fatigue, insomnia, headache, diminished libido, or rheumatologic symptoms. Psychological symptoms of the “climacteric” include depression and irritability. Some women continue to menstruate for many months despite symptoms of estrogen deficiency. The acute symptoms of estrogen deficiency noted above tend to gradually decline in severity. However, the median duration of moderate to severe hot flushes is about 10 years. Hot flushes tend to continue longer in thin versus obese women and in black versus white women. The late manifestations of estrogen deficiency include urogenital atrophy with vaginal dryness and dyspareunia; dysuria, frequency, and incontinence may occur. Increased bone osteoclastic activity increases the risk for osteoporosis and fractures. The skin becomes more wrinkled. Increases in the LDL:HDL cholesterol ratio cause an increased risk for arteriosclerosis.

A careful pelvic examination is always required to check for uterine or adnexal enlargement and to obtain a Papanicolaou smear and a vaginal smear for assessment of estrogen effect. Various life stresses, vigorous exercise, and “crash” dieting all predispose to amenorrhea; however, such factors should not be assumed to account for amenorrhea without a complete workup to screen for other causes.

Treatment

Therapy of symptomatic hypogonadism generally consists of estrogen replacement therapy (see below). Slow, deep breathing can ameliorate hot flushes. For women with severe hot flushes who cannot take estrogen, gabapentin is quite effective in oral doses titrated up to 200–800 mg every 8 hours. However, gabapentin is frequently associated with side effects such as fatigue, headache, dizziness, and cognitive impairment; such symptoms are most pronounced during the first 2 weeks of therapy but often improve within 4 weeks. An herb, black cohosh, may possibly relieve hot flushes. Tamoxifen and raloxifene offer bone protection but aggravate hot flushes. Treatment or prevention of postmenopausal osteoporosis with bisphosphonates such as alendronate, rismidronate, or intravenous zoledronic acid (see section on Osteoporosis) is another therapeutic option. Women with low serum testosterone levels may experience hypoactive sexual desire disorder (HSDD) that may respond to low-dose testosterone replacement.
Hormone Replacement Therapy

Two large, prospective studies have evaluated the effect of HRT on postmenopausal women. The Women’s Health Initiative (WHI) monitored 16,606 mostly-older postmenopausal women in the United States in a prospective, double-blinded, placebo-controlled study of postmenopausal HRT. A control group of women taking a daily placebo was compared with (1) women receiving daily conventional-dose oral combined HRT (conjugated equine estrogens [CEE] 0.625 mg/d with medroxyprogesterone acetate 2.5 mg/d) and (2) women, having had a hysterectomy, receiving only CEE 0.625 mg/d. The California Teachers Study prospectively followed up 71,237 postmenopausal women of all ages (mean age 63 years, range 36–94 years) for mortality, breast cancer, and other outcomes.

The WHI and California Teachers Study risk–benefit findings (described below) have dramatically changed postmenopausal HRT. The overall use of HRT has declined. When HRT is prescribed, lower-dose estrogen regimens are preferred over conventional-dose therapy. Estrogen preparations other than CEE have become increasingly favored. Transdermal and vaginal estrogen preparations are widely preferred over oral estrogen replacement. Also, the potential adverse effects of progestins are now recognized, such that women taking very low-dose estrogen replacement may not require progestins or may receive progestin therapy only periodically, if at all. For moderate- to high-dose estrogen therapy, progestins are used in lower doses. Also, clinicians are now tending to prescribe progesterone-eluting intrauterine devices and oral progestins other than medroxyprogesterone acetate.

A. Benefits of Estrogen Replacement Therapy

In the California Teachers Study, HRT in women under age 60 was associated with a dramatic 46% reduction in all-cause mortality, particularly cardiovascular disease. This association of HRT and lower mortality may suffer from self-selection bias. Nevertheless, there appears to be a survival advantage of HRT in women under age 60 that diminishes with age; no reduction in mortality was noted in the group of women aged 85–94 years. The reduction in cardiovascular disease among younger postmenopausal women taking HRT may be explained by the reduction in serum levels of atherogenic lipoprotein(a) with HRT, with or without a progestin. Improvement in serum HDL cholesterol is greatest with unopposed estrogen but is also seen with the addition of a progestin.

Estrogen replacement improves or eliminates postmenopausal hot flushes and diaphoretic episodes. Vaginal moisture is improved and libido is enhanced in some women. Estradiol vaginal rings can improve symptoms of an overactive bladder. Sleep disturbances are common in menopause and can be reversed with estrogen replacement. Some women notice a mild impairment in memory and cognitive function at menopause that can improve with HRT. Sex hormone replacement may also improve the body pain and reduced physical function experienced by some women at the time of menopause. Many women taking HRT experience a significantly improved quality of life. Estrogen replacement does not prevent facial skin wrinkling; however, it may improve facial skin moisture and thickness, reducing seborrhea and atrophy. Estrogen therapy does not appear to reduce the risk of Alzheimer dementia.

1. Estrogen replacement without progestin (unopposed HRT)—Interestingly, the WHI study found that postmenopausal women taking unopposed estrogen had a 23% reduction in breast cancer risk. The WHI study also found that women who received estrogen therapy experienced a reduced number of hip fractures (six fewer fractures/year per 10,000 women) compared with placebo. Even “microdose” transdermal estradiol (0.014 mg/d) improves bone density. Unopposed oral conjugated estrogens have no discernible effect upon cognitive function, overall mortality, or the risk for heart attacks, or colorectal cancer. Unopposed estrogen replacement improves glycemic control in women with type 2 diabetes mellitus. Perimenopause-related depression is improved by unopposed estrogen replacement; the addition of a progestin may negate this effect. A 20-year study of 8801 women living in a retirement community found that estrogen use was associated with improved survival. Age-adjusted mortality rates were 56.4 (per 1000 person-years) among nonusers and 50.4 among women who had used estrogen for 15 years or longer.

2. Estrogen replacement therapy with progestins (combined HRT)—Women receiving conventional-dose daily conjugated estrogen and medroxyprogesterone acetate (0.625 mg and 2.5 mg, respectively) for an average of 5.6 years, experienced a lower risk of developing diabetes mellitus (3.5%) versus those taking a placebo (4.2%).

B. Risks of Estrogen Replacement Therapy

The risks of estrogen replacement depend on the dose. Conventional doses (eg, oral conjugated estrogens ≥ 0.625 mg/d or transdermal estradiol ≥ 0.05 mg/d) carry higher risks than lower doses (eg, oral conjugated estrogens, ≤ 0.3 mg/d or transdermal estradiol ≤ 0.025 mg/d). Route of administration also affects risks, since oral estrogens pass through the liver and increase hepatic production of clotting factors (thereby increasing the risks of thrombotic stroke), whereas transdermal or vaginal administration of estrogen does not significantly increase clotting proclivity. The risks for HRT also depend on whether estrogen is administered alone (unopposed HRT) or with a progestin (combined HRT).

1. Estrogen replacement without progestin (unopposed HRT)—Surprisingly, the WHI study found that postmenopausal women who received conventional-dose estrogen-only therapy had a reduced risk of breast cancer (seven fewer cases/year per 10,000 women) compared with a placebo group. However, the California Teachers Study monitored women for a longer period; a group of 37,000 women who had been taking conventional-dose estrogen-only therapy for ≥ 20 years did have a slightly increased risk of breast cancer. Women taking lower-dose unopposed estrogen therapy would be expected to have lower long-term risk of breast cancer.
Conventional-dose unopposed estrogen replacement (0.625–1.25 mg daily) increases the risk of endometrial hyperplasia and dysfunctional uterine bleeding, which often prompts patients to stop the estrogen. However, lower-dose unopposed estrogen confers a much lower risk of dysfunctional uterine bleeding. Recurrent dysfunctional bleeding necessitates a pelvic examination and possibly an endometrial biopsy. There has been considerable concern that unopposed estrogen replacement might increase the risk for endometrial carcinoma. However, a Cochrane Database Review found no increased risk of endometrial carcinoma in a review of 30 randomized controlled trials. Therefore, lower-dose unopposed estrogen replacement does not appear to confer any increased risk for endometrial cancer.

Long-term conventional-dose unopposed estrogen increases the mortality risk from ovarian cancer, although the absolute risk is small. The annual age-adjusted ovarian cancer death rates for women taking estrogen replacement for $\geq 10$ years are 64:100,000 for current users, 38:100,000 for former users, and 26:100,000 for women who had never taken estrogen. Lower-dose estrogen replacement is believed to confer a negligible increased risk for ovarian cancer. The WHI trial was stopped in 2002 because of an increased risk of stroke among women taking conjugated oral estrogens in doses of 0.625 mg daily; the risk was about 44 strokes per 10,000 person-years versus about 32 per 10,000 person-years in women taking placebo. Transdermal or transvaginal estrogen is not expected to increase the risk of stroke.

Conventional-dose therapy with oral estrogen alone had been thought to increase the risk of deep venous thrombosis and stroke, but the WHI follow-up study found no such increased risk for deep venous thrombosis or stroke. Oral estrogens can cause hypertriglyceridemia, particularly in women with preexistent hyperlipidemia, rarely resulting in pancreatitis. Postmenopausal estrogen therapy also slightly increases the risk of gallstones and cholecystitis. Oral estrogens reduce the effectiveness of GH replacement. These side effects can be reduced or avoided by using non-oral estrogen replacement.

Elderly women, receiving long-term conventional-dose estrogen replacement, experience an increased risk of urinary incontinence. Some women complain of estrogen-induced edema or mastalgia. Estrogen replacement has been reported to lower the seizure threshold in some women with epilepsy. Untreated large pituitary prolactinomas may enlarge if exposed to estrogen.

2. Estrogen replacement with a progestin (combined HRT)—The WHI study found that women who received long-term conventional oral doses of combined HRT (conjugated estrogens 0.625 mg/d plus medroxyprogesterone acetate 2.5 mg/d) had an increased risk of deep venous thrombosis (3.5 per 1000 person-years) compared with women receiving placebo (1.7 per 1000 person-years).

Conventional-dose oral combined HRT results in an increased risk of myocardial infarction (24% or six additional heart attacks per 10,000 women), mostly in older women with high-risk LDL levels or preexistent coronary disease. Most of the risk for myocardial infarction occurs in the first year of therapy. This increased risk is attributable to the progestin component, since the estrogen-only arm of the WHI study found no increased risk of myocardial infarction.

Long-term conventional-dose oral combined HRT increases breast density and the risk for abnormal mammograms (9.4% versus 5.4% for placebo). There is also a higher risk of breast cancer (8 cases per 10,000 women/year versus 6.5 cases per 10,000 women/year for placebo); no increased risk of breast cancer has been found with estrogen-only HRT. This increased risk for breast cancer appears to mostly affect relatively thin women with a BMI < 24.4. The Iowa Women’s Health Study reported an increase in breast cancer with HRT only in women consuming more than 1 oz of alcohol weekly. No accelerated risk of breast cancer has been seen in users of HRT who have benign breast disease or a family history of breast cancer. Women in whom new-onset breast tenderness develops with combined HRT have an increased risk of breast cancer, compared with women without breast tenderness.

The Women’s Health Initiative Mental Study (WHIMS) followed the effect of combined conventional-dose oral HRT on cognitive function in women 65–79 years old. HRT did not protect these older women from cognitive decline. In fact, they experienced an increased risk for severe dementia at a rate of 23 more cases/year for every 10,000 women over age 65 years.

In the WHI study, women receiving conventional-dose combined oral HRT experienced an increased risk of stroke (31 strokes per 10,000 women/year versus 26 strokes per 10,000 women/year for placebo). Stroke risk was also increased by hypertension, diabetes, and smoking.

Women taking combined estrogen–progestin replacement do not experience an increased risk of ovarian cancer. They do experience an increased risk of developing asthma.

Progestins may cause moodiness, particularly in women with a history of premenstrual dysphoric disorder. Cycled progestins may trigger migraines in certain women. Many other adverse reactions have been reported, including breast tenderness, alopecia, and fluid retention. Contraindications to the use of progestins include thromboembolic disorders, liver disease, breast cancer, and pregnancy.

C. Hormone Replacement Therapy Agents

1. Transdermal estradiol—Estradiol can be delivered systemically with different systems of skin patches, mists, and gels. Transdermal estradiol works for most women, but some women have poor transdermal absorption or skin reactions to the product.

A. Estradiol patches mixed with adhesive—These systems tend to cause minimal skin irritation. Of the following preparations, the Vivelle-Dot patches are the smallest and least obtrusive. Generic estradiol transdermal (0.025, 0.0375, 0.05, 0.06, 0.075, 0.1 mg/d) is replaced once weekly. Brand products include Eslim, Vivelle, and Vivelle-Dot (0.025, 0.0375, 0.05, 0.075, or 0.1 mg/d), replaced twice weekly; Alora (0.025, 0.05, 0.075, or 0.1 mg/d), replaced twice weekly; Climara (0.025, 0.0375, 0.05, 0.06, 0.075, or 0.1 mg/d), replaced weekly; FemPatch (0.025 mg/d), replaced...
weekly; and Menostar (0.014 mg/d), replaced weekly. This type of estradiol skin patch can be cut in half and applied to the skin without proportionately greater loss of potency.

B. Estradiol patches with drug reservoir—These systems cause significant skin irritation in some women. Available preparations include Estraderm (0.05 or 0.1 mg/d), applied to the trunk, abdomen, or buttocks and replaced twice weekly.

C. Estradiol patches with progestin mixed with adhesive—These preparations mix estradiol with either norethindrone acetate or levonorgestrel. CombiPatch (0.05 mg E and 0.14 mg norethindrone acetate daily or 0.05 mg E and 0.25 mg norethindrone acetate daily) is replaced twice weekly. Climara Pro (0.45 mg E and 0.0125 mg levonorgestrel daily) is replaced once weekly. The addition of a progestin reduces the risk of endometrial hyperplasia but increases the risk of breast cancer and side effects, compared with estrogen therapy alone.

D. Estradiol gels and mists—EstroGel 0.06% is available in a metered-dose pump that dispenses 0.05 mg estradiol per actuation; estradiol doses are 0.05–0.1 mg/d. Elestrin 0.06% is available in a metered-dose pump that dispenses 0.5 mg estradiol per actuation; estradiol doses are 0.5–1 mg/d. These gels are applied daily to one arm from the wrist to the shoulder after bathing. Divigel 1% gel (0.025, 0.5, 1 g/packet) is applied to upper thigh daily. Estrasorb 1.7 g pouches (0.025 mg estradiol) is available in doses of 0.025–0.05 mg estradiol applied to the leg daily. Evamist is available as a topical mister that dispenses 1.53 mg estradiol/spray; doses are 1–3 sprays to the forearm daily. To avoid spreading the estradiol to others, the hands should be washed and precautions taken to avoid prolonged skin contact with children. Application of sunscreen prior to estradiol gel has been reported to increase the transdermal absorption of estradiol.

2. Oral estrogen—

A. Oral estrogen—only preparations—These preparations include conjugated equine estrogens (CEE 0.3, 0.45, 0.625, 0.9, 1.25 mg), conjugated plant-derived estrogens (eg, Menest, Estratab, 0.3, 0.625, and 2.5 mg), and conjugated synthetic estrogens (eg, Cenestin, 0.3, 0.625, 0.9, and 1.25 mg). Other preparations include ethinyl estradiol (20 and 50 mcg), estradiol (0.5, 1, and 2 mg), estradiol acetate (0.75, 1.5, 3, and 6 mg), and estradiol valerate (eg, Femtrace 0.45, 0.9, and 1.8 mg).

B. Oral estrogen plus progestin preparations—These include CEE with medroxyprogesterone acetate (Prempro 0.3/1.5, 0.45/1.5, 0.625/2.5, and 0.625 mg/5 mg), CEE for 14 days cycled with CEE plus medroxyprogesterone acetate for 14 days (Premphase 0.625/0 and 0.625 mg/5 mg), estradiol with norethindrone acetate (Activella 0.5/0 and 1 mg/0.5 mg), ethinyl estradiol with norethindrone acetate (Femhrt 2.5/5 and 5 mcg/1 mg), and estradiol with norgestimate (Prefest, sequences of estradiol 1 mg/d for 3 days, alternating with a combination of 1 mg estradiol/0.09 mg norgestimate daily for 3 days). Oral contraceptives can also be used for combined HRT.

3. Vaginal estrogen—Urogenital atrophy commonly develops in postmenopausal women and can cause dryness of the vagina, genital itching, burning, dyspareunia, and recurrent urinary tract infections. Urinary symptoms can include urgency and dysuria. Vaginal estrogen is intended to deliver estrogen directly to local tissues and is moderately effective in reducing these symptoms, while minimizing systemic estrogen exposure. Some estrogen is absorbed systematically and can relieve menopausal symptoms. Systemically absorbed estrogen avoids first-pass liver metabolism, causing less hypertriglyceridemia and prothrombotic effects than oral estrogen. Manufacturers recommend that these preparations be used for only 3–6 months in women with an intact uterus, since vaginal estrogen can cause endometrial proliferation. However, most clinicians use them for longer periods. Vaginal estrogen can be administered in three different ways: creams, tablets, and rings.

A. Estrogen vaginal creams—These creams are administered intravaginally with a measured-dose applicator daily for 2 weeks for atrophic vaginitis, then administered one to three times weekly. Available preparations include CEEs (Premarin, 0.626 mg/g cream), dosed as 0.25–0.5 g cream vaginally; dienestrol (Ortho Dienestrol, 10 mg/g cream), 0.25–0.5 g cream vaginally; estradiol (Estrace, 0.1 mg/g cream), 1 g cream vaginally; and estropipate (Ogen, 1.5 mg/g cream), 0.25–0.5 g vaginally.

B. Estradiol vaginal tablets—These tablets are sold prepackaged in a disposable applicator and can be administered deep intravaginally daily for 2 weeks for atrophic vaginitis, then twice weekly. The tablets dissolve into a gel that gradually releases estradiol. Available preparations include vaginal estradiol tablets (Vagifem, 25 mcg/tablet).

C. Estradiol vaginal rings—These rings are inserted manually into the upper third of the vagina, worn continuously, and replaced every 90 days. Only a small amount of the released estradiol enters the systemic circulation. Vaginal rings do not usually interfere with sexual intercourse. If a ring is removed or descends into the introitus, it may be washed in warm water and reinserted. Available preparations include Estrin (2 mg estradiol/ring, releasing 7.5 mcg/d) and Femring (12.4 mg estradiol/ring, releasing 0.05 mg/d, or 24.8 mg estradiol/ring, releasing 0.10 mg/d). For women with postmenopausal urinary urgency and frequency, even the low-dose Estrin can successfully reduce urinary symptoms.

D. Estradiol with progestin vaginal rings—NuvaRing contains a mixture of estradiol and etonogestrel. It is a contraceptive vaginal ring that is placed in the vagina for 3 weeks, removed for 1 week, then replaced.

4. Estradiol intramuscular—Parenteral estradiol should be used only for particularly severe menopausal symptoms when other measures have failed or are contraindicated. Estradiol cypionate (DepoEstradiol 5 mg/mL) may be administered intramuscularly in doses of 1–5 mg every 3–4 weeks. Estradiol valerate (20 mg/mL) may be administered intramuscularly in doses of 10–20 mg every 4 weeks. Women with an intact uterus should receive a progestin for the last 10 days of each cycle.
5. Oral progestins—For a woman with an intact uterus, long-term conventional-dose unopposed systemic estrogen therapy can cause endometrial hyperplasia, which typically results in dysfunctional uterine bleeding and might rarely lead to endometrial cancer. Progestin therapy transforms proliferative into secretory endometrium, causing a menopause when given intermittently or no bleeding when given continuously.

The type of progestin preparation, its dosage, and the timing of administration may be tailored to the given situation. Progestins may be given daily, monthly, or at longer intervals. When given episodically, progestins are usually administered for 7–14 day periods. Progestins are available in different formulations: Micronized progesterone (Prometrium, 100 mg/capsule), medroxyprogesterone acetate (Provera, Amen, Cycrin; 2.5, 5.0, and 10 mg/scored tablet), norethindrone acetate (Agestin, 5 mg/tablet), and norethindrone (Micronor, Nor-QD; 0.35 mg/tablet).

Topical progesterone (20–50 mg/d) may reduce hot flushes in women who are intolerant to oral HRT. It may be applied to the upper arms, thighs, or inner wrists daily. It may be compounded as micronized progesterone 250 mg/mL in a transdermal gel. Its effects upon the breast and endometrium are unknown.

6. Progestin-releasing intrauterine devices—Intrauterine devices (IUDs) that release progestins can be useful for women receiving ERT, since they can reduce the incidence of dysfunctional uterine bleeding and endometrial carcinoma without exposing women to the significant risks of systemic progestins. The Mirena IUD releases levonorgestrel and is inserted into the uterus by a clinician within 7 days of the onset of menses. It remains effective for up to 5 years. Parous women are generally better able to tolerate the Mirena IUD than nulliparous women.

7. Selective estrogen receptor modulators—SERMs (eg, raloxifene, tamoxifen) are an alternative to estrogen replacement for hypogonadal women at risk for osteoporosis who prefer not to take estrogens because of their contraindications (eg, breast or uterine cancer) or side effects. Raloxifene does not reduce hot flushes, vaginal dryness, skin wrinkling, or breast atrophy; it does not improve cognition. However, in doses of 60 mg/d orally, it inhibits bone loss without stimulating effects upon the breasts or endometrium. Because raloxifene may slightly increase the risk of venous thromboembolism, it should not be used by women at prolonged bed rest or by those prone to thrombosis. In contrast with the use of ERT, concomitant progestosterone therapy is not needed, and raloxifene does not increase the risk of development of breast cancer.

Tibolone (Livial) is an SERM whose metabolites have mixed estrogenic, progestogenic, and weak androgenic activity. It is comparable to HRT for the treatment of climacteric-related complaints. It does not appear to significantly stimulate proliferation of breast or endometrial tissue. It depresses both serum triglycerides and HDL cholesterol. Long-term studies are lacking. It is not available in the United States.

8. Phytoestrogens—These substances are found in plants that bind to estrogen receptors. Phytoestrogens, found in soy and red clover extracts, do not appear to significantly improve menopausal hot flushes, cognitive function, bone density, or plasma lipids.

9. Testosterone replacement therapy in women—In premenopausal women, serum testosterone levels decline with age. Between 25 and 45 years of age, women’s testosterone levels fall 50%. After natural menopause, the ovaries remain a significant source for testosterone. In fact, following natural menopause, serum testosterone levels do not fall abruptly and serum free testosterone levels may actually rise. In contrast, very low serum testosterone levels are found in women after bilateral oophorectomy, autoimmune ovarian failure, adenocarcinoma, and in hypopituitarism. Testosterone deficiency contributes to hot flushes, loss of sexual hair, muscle atrophy, osteoporosis, and diminished libido, also known as hypoactive sexual desire disorder.

In women, diminished libido is common and multifactorial. Although low serum testosterone levels may contribute to hypoactive sexual desire disorder, hysterectomy and sexual isolation are major causes. Low serum testosterone levels may also cause fatigue, a diminished sense of well-being, and a dulled enthusiasm for life. Androgen replacement may improve these problems.

Testosterone therapy is often effective, while DHEA therapy is not. Selected women may be treated with low-dose testosterone. Methyltestosterone can be taken orally in doses of 1.25–2.5 mg daily. Testosterone can also be compounded as a cream containing 1 mg/mL, with 1 mL applied to the low abdomen daily. Methyltestosterone is also available in combination with conjugated estrogens (eg, Estratest). This formulation is convenient but carries the same disadvantage as oral estrogen—increased risk of thromboembolism. Tablets contain either 1.25 mg conjugated estrogens with 2.5 mg methyltestosterone or 0.625 mg conjugated estrogens with 1.25 mg methyltestosterone. Estratest is usually started at the lowest strength. It should be given cyclically at the lowest dose that controls symptoms.

Women receiving testosterone therapy must be monitored for the appearance of any acne or hirsutism, and serum testosterone levels are determined periodically if women feel that they are benefiting and long-term testosterone therapy is instituted. Side effects of low-dose testosterone therapy are usually minimal but may include polycythemia, emotional changes, hirsutism, acne, an adverse effect on lipids, and potentiation of warfarin anticoagulation therapy. Testosterone replacement tends to reduce both triglyceride and HDL cholesterol levels. Hepatocellular neoplasms and peliosis hepatis, rare complications of oral androgens at higher doses, have not been reported with methyltestosterone at lower doses of 2.5 mg orally daily. Androgens should not be given to women with liver disease or during pregnancy or breast-feeding. Testosterone replacement therapy for women should be used judiciously, since long-term prospective clinical trials are lacking. An analysis of the Nurses’ Health Study found that women who had been taking CEEs plus methyltestosterone experienced an increased risk of breast cancer. Yearly mammography is recommended for all women over 40 years of age.
D. Other Treatments for Menopausal Hot Flashes

**Lifestyle changes**, such as dressing coolly, keeping the ambient room temperature cool, sleeping with light bed-clothes, sipping cold beverages, and stress reduction may help reduce hot flushes. Women may try avoiding known triggers for hot flushes, such as smoking, alcohol, caffeine, and hot spicy foods. Idiosyncratic triggers for hot flushes may be discerned and avoided. **Gabapentin** can relieve hot flushes when estrogen replacement therapy is contraindicated or not desired and when lifestyle changes are insufficient. Women with moderate to severe postmenopausal flushes may obtain relief with gabapentin 600–2400 mg daily in divided doses. Side effects are most prominent in the first 2 weeks of treatment and may include somnolence, unsteadiness, and dizziness.

---

**TURNER SYNDROME (Gonadal Dysgenesis)**

**Essentials of Diagnosis**
- Short stature with normal GH levels.
- Primary amenorrhea or early ovarian failure.
- Epicanthal folds, webbed neck, short fourth metacarpals.
- Renal and cardiovascular anomalies.

---

Turner syndrome comprises a group of X chromosome disorders that are associated with spontaneous abortion, primary hypogonadism, short stature, and other phenotypic anomalies. It affects 1–2% of fetuses, of which about 97% abort, accounting for about 10% of all spontaneous abortions. Nevertheless, it affects about 1 in every 2500 live female births. Patients with the classic syndrome (about 50% of cases) lack one of the two chromosomes (45,XO karyotype). Other patients with Turner syndrome have X chromosome abnormalities, such as ring X or Xq (X/abnormal X) or X chromosome deletions affecting all or some somatic cells (mosaicism, XX/XO). Turner syndrome may be diagnosed in infant girls at birth, since they tend to be small and may exhibit severe lymphedema. Evaluation for childhood short stature often leads to the diagnosis. Girls and women with Turner syndrome have an increased risk of aortic coarctation (11%) and bicuspid aortic valves (16%); these cardiac abnormalities are more common in patients with webbed necks.

---

**1. Classic Turner Syndrome (45,XO Gonadal Dysgenesis)**

#### Clinical Findings

**A. Symptoms and Signs**

Features of Turner syndrome are variable and may be subtle in girls with mosaicism. Typical manifestations in adulthood include short stature, hypogonadism, webbed neck, high-arched palate, wide-spaced nipples, hypertension, and renal abnormalities (Table 26–16). Emotional disorders are common.

Hypogonadism presents as “delayed adolescence” (primary amenorrhea, 80%) or early ovarian failure (20%); girls with 45,XO Turner (blood karyotyping) who enter puberty are typically found to have mosaicism if other tissues are karyotyped.

**B. Laboratory Findings**

Hypogonadism is confirmed in girls who have high serum levels of FSH and LH. A blood karyotype showing 45,XO or X chromosome abnormalities or mosaicism establishes the diagnosis. GH and IGF-1 levels are normal.

**C. Imaging**

An ultrasound and MRI scan of the chest and abdomen should be done in all patients with Turner syndrome to determine whether cardiac, aortic, and renal abnormalities are present.

---

**Treatment**

Treatment of short stature with daily injections of GH (0.1 unit/kg/d) plus an androgen (eg, oxandrolone) for at least 4 years before epiphyseal fusion increases final height by a mean of about 10.3 cm over the mean predicted height of 144.2 cm. Such GH treatment rarely causes pseudotumor cerebri. After age 12 years, estrogen therapy is begun with...
low doses of conjugated estrogens (0.3 mg) or ethinyl estradiol (5 mcg) given on days 1–21 per month. When growth stops, HRT is begun with estrogen and progestin; transdermal estrogen may be used to initiate pubertal development.

## Complications & Surveillance

Bicuspid aortic valves are associated with an increased risk of infective endocarditis, aortic valvular stenosis or insufficiency, and ascending aortic aneurysm and dissection.

Partial anomalous pulmonary vein connections occur in 13% and can lead to left-to-right shunting of blood. Adults with Turner syndrome have a high incidence of ECG abnormalities.

Women with Turner syndrome have a reduced life expectancy due in part to their increased risk of diabetes mellitus (types 1 and 2), hypertension, dyslipidemia, and osteoporosis.

Diagnostic vigilance and aggressive treatment of these conditions reduce the risk of aortic aneurysm dissection, ischemic heart disease, stroke, and fracture. Patients are prone to keloid formation after surgery or ear piercing. Yearly ocular examinations and periodic thyroid evaluations are recommended.

Repeat cardiovascular evaluations should be done every 3–4 years. Patients with the classic 45,XO karyotype have a high risk of renal structural abnormalities, whereas those with 46 X/abnormal X are more prone to malformations of the urinary collecting system. The risk of aortic dissection is increased more than 100-fold in women with Turner syndrome, particularly those with pronounced neck webbing and shield chest. Patients with aortic root enlargement are usually treated with β-blockade and serial imaging. Women with Turner syndrome who are able to become pregnant are strongly advised to deliver via cesarean section due to the risk of aortic aneurysm rupture during vaginal delivery.

### 2. Turner Syndrome Variants

#### A. 46,X (Abnormal X) Karyotype

Patients with small distal short arm deletions of the X chromosome (Xp-) that include the **SHOX** gene often have short stature and skeletal abnormalities but have a low risk of ovarian failure. Transmission of Turner syndrome from mother to daughter can occur. There may be an increased risk of trisomy 21 in the conceptuses of women with Turner syndrome. Patients with deletions of the long arm of the X chromosome (distal to Xq24) often have amenorrhea without short stature or other features of Turner syndrome. Abnormalities or deletions of other genes located on both the long and short arms of the X chromosome can produce gonadal dysgenesis with few other somatic features.

#### B. 45,XO/46,XX Mosaicism

This karyotype results in a modified form of Turner syndrome. Such girls tend to be taller and may have more gonadal function and fewer other manifestations of Turner syndrome.

#### C. Other Variants

45,XO/46,XY mosaicism can produce some manifestations of Turner syndrome. Patients may have ambiguous genitalia or male infertility with an otherwise normal phenotype. Germ cell tumors, such as gonadoblastomas and seminomas, develop in about 10% of patients with 45,XO/46,XY mosaicism; most such tumors are benign.

---

</table>
1. MEN 1 (Wermer Syndrome)

MEN 1 is a familial multiglandular endocrine tumor syndrome, with a prevalence of 2–10 per 100,000 people. The presentation of MEN 1 is quite variable, even in the same kindred. Parathyroid, enteropancreatic, and pituitary tumors can be present in one individual, though not necessarily at the same time. Nonendocrine tumors also occur, such as subcutaneous lipomas, facial angiofibromas, and collagenomas. In some affected individuals, tumors may start developing in childhood, whereas in others, tumors develop late in adult life.

About 90% of patients with MEN 1 have germline mutations that are inherited as an autosomal dominant trait. Patients with MEN 1 usually have detectable mutations in the \textit{menin} gene, located on the long arm of chromosome 11 (11q13). MEN 1 gene testing is available at a few centers and is able to detect the specific mutation in 60–95% of cases. If no mutation is detected, genetic linkage analysis can be done if there are several affected members in the kindred. Gene testing permits the rest of the kindred to be tested for the specific gene defect and allows informed genetic counseling.

With close endocrine surveillance of affected individuals, the initial biochemical manifestations (usually hypercalcemia) can often be detected as early as age 14–18 years in patients with a MEN 1 gene mutation, although clinical manifestations do not usually present until the third or fourth decade.

Hyperparathyroidism is the first clinical manifestation of MEN 1 in two-thirds of affected patients, but it may present at any time of life. Patients with the MEN 1 mutation have a > 90% lifetime risk of developing hyperparathyroidism. The hyperparathyroidism of MEN 1 is notoriously difficult to treat surgically, due to multiple gland involvement and the frequency of supernumerary glands and ectopic parathyroid tissue. Typically, three and one-half glands are resected, leaving one-half of the most normal-appearing gland intact. Also, during neck surgery, a thymectomy is performed to resect any intrathyrmic parathyroid glands or

</tbody>
</table>
occult thymic carcinoid tumors. Nevertheless, the surgical failure rate is about 38%, and there is a recurrence rate of about 16%, with hypercalcemia often recurring many years after neck surgery. Aggressive parathyroid resection can cause permanent hypocalcemia. Patients with persistent or recurrent hyperparathyroidism should avoid oral calcium supplements and thiazide diuretics; oral therapy with calcimimetic drug, such as cinacalcet, is effective but expensive. The diagnosis and treatment of hyperparathyroidism is described earlier in this chapter.

Enteropancreatic tumors occur in about 75% of patients with MEN 1. Nonsecretory neuroendocrine tumors occur and do not secrete hormones; they tend to be large and very aggressive. Gastrinomas occur in about 35% of patients with MEN 1; they secrete gastrin, thereby causing severe gastric hyperacidity (Zollinger–Ellison syndrome) with peptic ulcer disease or diarrhea. Concurrent hypercalcemia, due to hyperparathyroidism (see above), stimulates gastrin and gastric acid secretion; control of the hypercalcemia often reduces gastric acid secretion and serum gastrin levels. These gastrinomas tend to be small, multiple, and ectopic; they are frequently found outside the pancreas, usually in the duodenum. Gastrinomas of MEN 1 can metastasize to the liver; but in patients with MEN 1, depending upon the kindred, hepatic metastases tend to be less aggressive than those from sporadic gastrinomas. Treatment of patients with gastrinomas in MEN 1 is usually conservative, utilizing long-term high-dose proton pump inhibitor therapy and control of hypercalcemia; surgery is palliative and usually reserved for aggressive gastrinomas and those tumors arising in the duodenum. Zollinger–Ellison syndrome is also discussed in Chapter 15.

Insulinomas cause hyperinsulinism and fasting hypoglycemia. They occur in about 15% of patients with MEN 1. Surgery is usually attempted, but the tumors can be small, multiple, and difficult to detect. The diagnosis and treatment of insulinomas are described in Chapter 27. Glucagonomas (1.6%) secrete glucagon and cause diabetes and migratory necrotic erythema. VIPomas (1%) secrete VIP and cause profuse watery diarrhea, hypokalemia, and achlorhydria (WDHA, Verner-Morrison syndrome). Somatostatinomas (0.7%) can cause diabetes mellitus, steatorrhea, and cholelithiasis.

Pituitary adenomas occur in about 42% of patients with MEN 1. They are more common in women (50%) than men (31%) and are the presenting tumor in 17% of patients with MEN 1. These tumors tend to be more aggressive macroadenomas (> 1 cm diameter, 85%) compared to sporadic pituitary tumors (42%). Of MEN 1–associated pituitary tumors, about 62% secrete PRL, 8% secrete GH, 13% secrete both PRL and GH, and 13% are nonsecretory; only 4% secrete ACTH and cause Cushing disease. The diagnosis and treatment of pituitary tumors and Cushing disease were described earlier in this chapter. These pituitary tumors can produce local pressure effects and hypopituitarism.

Adrenal adenomas or hyperplasia occurs in about 37% of patients with MEN 1 and 50% are bilateral. They are generally benign and nonfunctional. In one series, one out of 12 of these patients developed a feminizing adrenal carcinoma. These adrenal lesions are pituitary independent.

Nonendocrine tumors occur commonly in MEN 1. Small facial angiofibromas and subcutaneous lipomas are common. Collagenomas can present as firm dermal nodules. Malignant melanomas have been reported.

The differential diagnosis of MEN 1 includes sporadic or familial tumors of the pituitary, parathyroids, or pancreatic islets. Hypercalcemia (from any cause) may cause gastrointestinal symptoms and increased gastrin levels, simulating a gastrinoma. Routine suppression of gastric acid secretion with H₂-blockers or proton pump inhibitors causes a physiologic increase in serum gastrin that can be mistaken for a gastrinoma. H₂-blockers and metoclopramide cause hyperprolactinemia, simulating a pituitary prolactinoma.

Variants of MEN 1 also occur. Kindreds with MEN 1 Burin variant have a high prevalence of pheochromocytomas, late-onset hyperparathyroidism, and carcinoid tumors, but rarely enteropancreatic tumors.

2. MEN 2A (Sipple Syndrome)

MEN 2A is a rare familial multiglandular syndrome that is inherited as an autosomal dominant trait. Patients with MEN 2A should have genetic testing for a ret protooncogene (RET) mutation. Their first-degree relatives may then be tested for the specific RET mutation. Patients with MEN 2A may have medullary thyroid carcinoma (> 90%); hyperparathyroidism (20–50%), due to hyperplasia or multiple adenomas in over 70% of cases; pheochromocytomas (20–35%), which are often bilateral; or Hirschsprung disease. The medullary thyroid carcinoma is of mild to moderate aggressiveness. Children harboring an MEN 2A RET gene mutation are advised to have a prophylactic total thyroidectomy by age 6 years.

Siblings or children of patients with MEN 2A should have genetic testing to determine if they have a mutation of the ret protooncogene (RET) on chromosome 10cen10q11.2; this identifies about 95% of affected individuals. Each kindred has a certain ret codon mutation that correlates with the particular variation in the MEN 2 syndrome, such as the age of onset and aggressiveness of medullary thyroid cancer. The specific mutation as well as case histories of family members should guide the timing for prophylactic thyroidectomy. Before any surgical procedure, MEN 2 carriers should be screened for pheochromocytoma. There is incomplete penetrance, and about 30% of those with such mutations never manifest endocrine tumors.

Patients may be screened for medullary thyroid carcinoma with a serum calcitonin drawn after 3 days of omeprazole, 20 mg orally twice daily; calcitonin levels rise in the presence of medullary thyroid carcinoma to above 80 pg/mL in women or above 190 pg/mL in men.

3. MEN 2B

MEN 2B is a familial, autosomal dominant multiglandular syndrome that is caused by a mutation of the ret protooncogene (RET) on chromosome 10. MEN 2B is characterized by mucosal neuromas (> 90%) with bumpy and enlarged lips and tongue, Marfan-like habitus (75%), adrenal pheochromocytomas (60%) that are rarely malignant and often bilateral, and medullary thyroid carcinoma.
(80%). Patients also have intestinal abnormalities (75%) such as intestinal ganglioneuromas, skeletal abnormalities (87%), and delayed puberty (43%). Medullary thyroid carcinoma is aggressive and presents early in life. Therefore, infants having a parent with MEN 2B receive genetic screening; those carrying the RET mutation undergo a prophylactic total thyroidectomy by age 6 months.

**OTHER SYNDROMES OF MULTIPLE ENDOCRINE NEOPLASIA**

Patients with Carney complex develop tumors in the adrenal cortex, pituitary, thyroid, and gonads as well as cardiac myxomas and hyperpigmentation. Patients with Cowden disease develop thyroid abnormalities (66%) such as benign adenomas and follicular adenocarcinomas, along with breast cancer (20–36% in women), and multiple hamartomas that affect the skin and multiple other organs. Patients with McCune-Albright syndrome may develop precocious puberty (particularly girls) due to gonadal hypersecretion. Cushing syndrome caused by multiple adrenal nodules, hyperthyroidism from hypersecretory thyroid nodules, and acromegaly caused by GH-secreting pituitary tumors. Patients have fibrous dysplasia of bones and hypophosphatemia, with bone fractures being common. Sudden death has been reported. It is caused by a postzygotic somatic mutation in the gene encoding the stimulatory Gs protein, resulting in constitutive activation of affected cells.

*Hydrocortisone = 1 in potency.*

---

### Mechanisms of Action

Cortisol is a steroid hormone that is normally secreted by the adrenal cortex in response to ACTH. It exerts its action by binding to nuclear receptors, which then act upon chromatin to regulate gene expression, producing effects throughout the body.

### Relative Potencies (Table 26–18)

Hydrocortisone and cortisone acetate, like cortisol, have mineralocorticoid effects that become excessive at higher doses. Other synthetic corticosteroids such as prednisone, dexamethasone, and deflazacort (an oxazoline derivative of prednisolone) have minimal mineralocorticoid activity. Anticonvulsant drugs (e.g., phenytoin, carbamazepine, phenobarbital) accelerate the metabolism of corticosteroids other than hydrocortisone, making them significantly less potent. Megestrol, a synthetic progestin, has slight corticosteroid activity that becomes significant when administered in high doses for appetite stimulation.

### Adverse Effects

Prolonged treatment with systemic high-dose corticosteroids causes a variety of adverse effects that can be life-threatening. Patients should be thoroughly informed of the major possible side effects of treatment such as insomnia, cognitive and personality changes, weight gain with central obesity, bruising, striae, muscle weakness, polyuria, kidney stones, diabetes mellitus, glaucoma, cataracts, sex hormone suppression, candidiasis and opportunistic infections. High-dose corticosteroids have adverse cardiovascular effects, increasing the risk of hypertension, dyslipidemia, myocardial infarction, stroke, atrial fibrillation or flutter, and heart failure. Bone fractures (especially spine and hip) ultimately occur in about 40% of patients receiving long-term corticosteroid therapy. Osteoporotic fractures can also occur in patients who receive extensive topical, inhaled, or intermittent oral corticosteroids (e.g., prednisone ≥ 10 mg daily and cumulative dose > 1 g). Osteoporotic fractures can occur even in patients receiving long-term corticosteroid therapy at relatively low doses (e.g., 5–7.5 mg prednisone daily). Patients at increased risk for corticosteroid osteoporotic fractures include those who are over age 60 or who have a low body mass index, pretreatment osteoporosis, a family history of osteoporosis, or concurrent disease that limits mobility. Avascular necrosis of bone (especially hips) develops in about 15% of patients who...

receive corticosteroids at high doses (eg, prednisone ≥ 15 mg daily) for more than 1 month with cumulative prednisone doses of ≥ 10 g.

Bisphosphonates (eg, alendronate, 70 mg orally weekly) prevent the development of osteoporosis among patients receiving prolonged courses of corticosteroids. For patients who are unable to tolerate oral bisphosphonates (due to esophagitis, hiatal hernia, or gastritis), periodic intravenous infusions of pamidronate, 60–90 mg, or zoledronic acid, 2–4 mg, should also be effective. Teriparatide, 20 mcg subcutaneously daily for up to 2 years, is also effective against corticosteroid-induced osteoporosis. (See further discussion in Osteoporosis section.) It is wise to follow an organized treatment plan such as the one outlined in Table 26–19.

Diabetes Mellitus & Hypoglycemia

Umesh Masharani, MB, BS, MRCP(UK)

Type 1 diabetes:
- Polyuria, polydipsia, and weight loss associated with random plasma glucose ≥ 200 mg/dL (11.1 mmol/L).
- Plasma glucose of ≥ 126 mg/dL (7.0 mmol/L) after an overnight fast, documented on more than one occasion.
- Ketonemia, ketonuria, or both.
- Islet autoantibodies are frequently present.

Type 2 diabetes:
- Most patients are over 40 years of age and obese.
- Polyuria and polydipsia. Ketonuria and weight loss generally are uncommon at time of diagnosis. Candidal vaginitis in women may be an initial manifestation. Many patients have few or no symptoms.
- Plasma glucose of ≥ 126 mg/dL after an overnight fast on more than one occasion. Two hours after 75 g oral glucose, diagnostic values are ≥ 200 mg/dL (11.1 mmol).
- Hypertension, dyslipidemia, and atherosclerosis are often associated.

Classification & Pathogenesis

Diabetes mellitus is a syndrome with disordered metabolism and inappropriate hyperglycemia due to either a deficiency of insulin secretion or to a combination of insulin resistance and inadequate insulin secretion to compensate. Type 1 diabetes is due to pancreatic islet B cell destruction predominantly by an autoimmune process, and these patients are prone to ketoacidosis. Type 2 diabetes is the more prevalent form and results from insulin resistance with a defect in compensatory insulin secretion.

A. Type 1 Diabetes Mellitus

This form of diabetes is immune-mediated in over 95% of cases (type 1a) and idiopathic in < 5% (type 1b). The rate of pancreatic B cell destruction is quite variable, being rapid in some individuals and slow in others. Type 1 diabetes is usually associated with ketosis in its untreated state. It occurs at any age but most commonly arises in children and young adults with a peak incidence before school age and again at around puberty. It is a catabolic disorder in which circulating insulin is virtually absent, plasma glucagon is elevated, and the pancreatic B cells fail to respond to all insulinogenic stimuli. Exogenous insulin is therefore required to reverse the catabolic state, prevent ketosis, reduce the hyperglucagonemia, and reduce blood glucose.

1. Immune-mediated type 1 diabetes mellitus (type 1A) — The highest incidence of immune-mediated type 1 diabetes mellitus is in Scandinavia and northern Europe, where the annual incidence is as high as 40 per 100,000 children aged 14 years or younger in Finland, 31 per 100,000 in Sweden, 22 per 100,000 in Norway, and 20 per 100,000 in England. The annual incidence of type 1 diabetes decreases across the rest of Europe to 11 per 100,000 in Greece and 9 per 100,000 in France. Surprisingly, the island of Sardinia has as high an annual incidence as Finland.
(40 per 100,000) even though in the rest of Italy, including the island of Sicily, it is only 11 per 100,000 per year. In the United States, the annual incidence of type 1 diabetes averages 16 per 100,000, with higher rates in states more densely populated with persons of Scandinavian descent such as Minnesota. Worldwide, the lowest incidence of type 1 diabetes (< 1 case per 100,000 per year) is in China and parts of South America. The global incidence of type 1 diabetes is increasing (approximately 3% each year). In Europe, the highest annual incidence increase was seen in low prevalence countries in Eastern Europe, especially Romania and Poland. Changes in environmental factors most likely explain this increased incidence.

Approximately one-third of the disease susceptibility is due to genes and two-thirds to environmental factors. Genes that are related to the HLA locus contribute about 40% of the genetic risk. About 95% of patients with type 1 diabetes possess either HLA-DR3 or HLA-DR4, compared with 45–50% of white controls. HLA-DQ genes are even more specific markers of type 1 susceptibility, since a particular variety (HLA-DQB1*0302) is found in the DR4 patients with type 1, while a “protective” gene (HLA-DQB1*0602) is often present in the DR4 controls. The other important gene that contributes to about 10% of the genetic risk is found at the 5’ polymorphic region of the insulin gene. This polymorphic region affects the expression of the insulin gene in the thymus and results in depletion of insulin-specific T lymphocytes. In linkage studies, 16 other genetic regions of the human genome have been identified as being important to pathogenesis. Many of the genes linked to these additional loci play important roles in the function and regulation of the immune response. Mutations in genes associated with T cell tolerance can also cause autoimmune diabetes. The autoimmune regulatory gene (AIRE) product regulates the expression of several proteins in the thymus causing the deletion of self-reactive T cells. Type 1 diabetes mellitus as well as other autoimmune disorders

MODY, maturity-onset diabetes of the young.

(automatic polyglandular syndrome 1) develop in 20% of individuals with homozygote mutations in AIRE. FOXP3, an X chromosome gene, encodes a transcription factor required for the formation of regulatory T cells. Mutations in FOXP3 lead to very early type 1 diabetes mellitus and other autoimmune endocrinopathies (immuno-dysregulation polyendocrinopathy enteropathy X-linked [IPEX] syndrome). Most patients with type 1 diabetes mellitus have circulating antibodies to islet cells (ICA), insulin (IAA), glutamic acid decarboxylase 65 (GAD65), tyrosine phosphatase IA2 (ICA-512), and zinc transporter 8 (ZnT8) at the time the diagnosis is made (Table 27–2). These antibodies facilitate screening for an autoimmune cause of diabetes, particularly screening siblings of affected children, as well as adults with atypical features of type 2 diabetes mellitus. Screening with GAD65, ICA-512, IAA, and ZnT8 autoantibodies may identify about 98% of people who have an autoimmune basis for their beta cell loss. Antibody levels decline with increasing duration of disease. Also, low levels of anti-insulin antibodies develop in almost all patients once they are treated with insulin.

Family members of diabetic probands are at increased lifetime risk for developing type 1 diabetes mellitus. A child whose mother has type 1 diabetes has a 3% risk of developing the disease and a 6% risk if the child’s father has it. The risk in siblings is related to the number of HLA haplotypes that the sibling shares with the diabetic proband. If one haplotype is shared, the risk is 6% and if two haplotypes are shared, the risk increases to 12–25%. The highest risk is for identical twins, where the concordance rate is 25–50%.

Some patients with a milder expression of type 1 diabetes mellitus initially retain enough B cell function to avoid ketosis, but as their B cell mass diminishes later in life, dependence on insulin therapy develops. Islet cell antibody surveys among northern Europeans indicate that up to 15% of “type 2” diabetic patients may actually have this mild form of type 1 diabetes (latent autoimmune diabetes of adulthood; LADA). Evidence for environmental factors playing a role in the development of type 1 diabetes include the observation that the disease is more common in Scandinavian countries and becomes progressively less frequent in countries nearer and nearer to the equator. Also, the risk for type 1 diabetes increases when individuals who normally have a low risk emigrate to the Northern Hemisphere. For example, it was recently shown that Pakistani children born and raised in Bradford, England have a higher risk for

developing type 1 diabetes compared with children who lived in Pakistan all their lives.

Which environmental factor is responsible for the increased risk is not known. There have been a number of different hypotheses including infections with certain viruses (mumps, rubella, Coxsackie B4) and consumption of cow’s milk. Also, in developed countries, childhood infections have become less frequent and so perhaps the immune system becomes dysregulated with development of autoimmunity and conditions such as asthma and diabetes. This theory is referred to as the hygiene hypothesis. None of these factors has so far been confirmed as the culprit. Part of the difficulty is that autoimmune injury undoubtedly starts many years before clinical diabetes mellitus develops.

2. Idiopathic type 1 diabetes mellitus (type 1B)—

Approximately 5% of subjects have no evidence of pancreatic B cell autoimmunity to explain their insulinopenia and ketoadiposis. This subgroup has been classified as “idiopathic type 1 diabetes” and designated as “type 1B.” Although only a minority of patients with type 1 diabetes fall into this group, most of these are of Asian or African origin. It was recently reported that about 4% of the West Africans with ketosis-prone diabetes are homozygous for a mutation in \( \text{PAX-4} \) (Arg133Trp)—a transcription factor that is essential for the development of pancreatic islets.

B. Type 2 Diabetes Mellitus

This represents a heterogeneous group of conditions that used to occur predominantly in adults, but it is now more frequently encountered in children and adolescents. More than 90% of all diabetic persons in the United States are included under this classification. Circulating endogenous insulin is sufficient to prevent ketoacidosis but is inadequate to prevent hyperglycemia in the face of increased needs owing to tissue insensitivity (insulin resistance).

Genetic and environmental factors combine to cause both the insulin resistance and the beta cell loss. Most epidemiologic data indicate strong genetic influences, since in monozygotic twins over 40 years of age, concordance develops in over 70% of cases within a year whenever type 2 diabetes develops in one twin. Genome-wide association studies have made considerable progress in identifying the at-risk genes. So far, 19 different genetic loci have been reported that about 4% of the West Africans with diabetes mellitus are homozygous for a mutation in \( \text{PAX-4} \) (Arg133Trp)—a transcription factor that is essential for the development of pancreatic islets.

C. Other Specific Types of Diabetes Mellitus

1. Maturity-onset diabetes of the young (MODY)—

This subgroup is a relatively rare monogenic disorder characterized by non–insulin-dependent diabetes with autosomal dominant inheritance and an age at onset of 25 years or younger. Patients are nonobese, and their hyperglycemia is due to impaired glucose-induced secretion of insulin. Six types of MODY have been described. Except for MODY 2, in which a glucokinase gene is defective, all other types involve mutations of a nuclear transcription factor that regulates islet gene expression.

The enzyme glucokinase is a rate-limiting step in glycolysis and determines the rate of adenosine triphosphate (ATP) production from glucose and the insulin secretory response in the beta cell. MODY 2, due to glucokinase mutations, is usually quite mild, associated with only slight fasting hyperglycemia and few if any microvascular diabetic complications. It generally responds well to hygienic measures or low doses of oral hypoglycemic agents. MODY 3, due to mutations in hepatic nuclear factor \( \alpha \) is the most common form, accounting for two-thirds of all MODY
cases. The clinical course is of progressive beta cell failure and need for insulin therapy. Mutations in both alleles of glucokinase present with more severe neonatal diabetes. Mutation in one allele of the pancreatic duodenal homebox 1 (PDX1) causes diabetes usually at a later age (~35 years) than other forms of MODY; mutations in both alleles of PDX1 causes pancreatic agenesis.

2. Diabetes due to mutant insulins—This is a very rare subtype of nonobese type 2 diabetes, with no more than ten families having been described. Since affected individuals were heterozygous and possessed one normal insulin gene, diabetes was mild, did not appear until middle age, and showed autosomal dominant genetic transmission. There is generally no evidence of clinical insulin resistance, and these patients respond well to standard therapy.

3. Diabetes due to mutant insulin receptors—Defects in one of their insulin receptor genes have been found in more than 40 people with diabetes, and most have extreme insulin resistance associated with acanthosis nigricans (Figures 27–1 and 27–2). In very rare instances when both insulin receptor genes are abnormal, newborns present with a leprechaun-like phenotype and seldom live through infancy.

4. Diabetes mellitus associated with a mutation of mitochondrial DNA—Since sperm do not contain mitochondria, only the mother transmits mitochondrial genes to her offspring. Diabetes due to mutations of mitochondrial DNA occurs in < 2% of patients with diabetes. The most common cause is the A3243G mutation in the gene coding for the tRNA (Leu,UUR). Diabetes occurs even when a small percentage of the mitochondria in the cell carry the mutation; the heteroplasmy levels in the leukocytes range from 1% to 40%. Diabetes usually develops in these patients in their late 30s, and characteristically, they also have hearing loss (maternally inherited diabetes and deafness [MIDD]). In some patients, the beta cell failure can be rapidly progressive and patients require insulin soon after diagnosis. Other patients can be managed by diet or oral agents for a while but most eventually require insulin. MIDD patients are not usually overweight; they resemble patients with type 1 diabetes mellitus but without evidence for autoimmunity.

5. Wolfram syndrome—Wolfram syndrome is an autosomal recessive neurodegenerative disorder first evident in childhood. It consists of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness, hence the acronym DIDMOAD. It is due to mutations in a gene named WFS1, which encodes a 100.3 KDa transmembrane protein localized in the endoplasmic reticulum. The WFS1 protein forms part of the unfolding protein response and helps protect the beta cells from endoplasmic reticulum stress and apoptosis especially during periods of high insulin demand. Diabetes develops in mice with mutated form of this protein; and isolated islets from these mice show impairment in insulin secretion to glucose stimulus and increased apoptosis. The diabetes mellitus usually presents in the first decade together with the optic atrophy. Cranial diabetes insipidus and sensorineural deafness develop during the second decade in 60–75% of patients. Ureterohydronephrosis, neurogenic bladder, cerebellar ataxia, peripheral neuropathy, and psychiatric illness develop later in many patients.

6. Autosomal recessive syndromes—Homozygous mutations in a number of pancreatic transcription factors, NEUROG3, PTF1A, RFX6, and GLI-similar 3 (GLIS3), cause neonatal or childhood diabetes. Homozygous PTF1A mutations result in absent pancreas and cerebellar atrophy; NEUROG3 mutations cause severe malabsorption and diabetes before puberty. Homozygous mutations in RFX6 cause the Mitchell-Riley syndrome characterized by absence of all islet cell types apart from pancreatic polypeptide cells, hypoplasia of the pancreas and gallbladder, and intestinal atresia. GLIS3 gene plays a role in transcription of insulin
Table 27–3. Secondary causes of hyperglycemia.

| Hyperglycemia due to tissue insensitivity to insulin | Hormonal tumors (acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma) |
| Pharmacologic agents (corticosteroids, sympathomimetic drugs, niacin) |
| Liver disease (cirrhosis, hemochromatosis) |
| Muscle disorders (myotonic dystrophy) |
| Adipose tissue disorders (lipodystrophy, truncal obesity) |
| Insulin receptor disorders (acanthosis nigricans syndromes, lipoedema) |

Hyperglycemia due to reduced insulin secretion

| Hormonal tumors (somatostatinoma, pheochromocytoma) |
| Pancreatic disorders (pancreatitis, hemosiderosis, hemochromatosis) |
| Pharmacologic agents (thiazide diuretics, phenytoin, pentamidine) |

7. Diabetes mellitus secondary to other causes—Endocrine tumors secreting growth hormone, glucocorticoids, catecholamines, glucagon, or somatostatin can cause glucose intolerance (Table 27–3). In the first four of these situations, peripheral responsiveness to insulin is impaired. With excess of glucocorticoids, catecholamines, or glucagon, increased hepatic output of glucose is a contributory factor; in the case of catecholamines, decreased insulin release is an additional factor in producing carbohydrate intolerance, and with somatostatin, inhibition of insulin secretion is the major factor. Diabetes mainly occurs in individuals with underlying defects in insulin secretion, and hyperglycemia typically resolves when the hormone excess is resolved.

A rare syndrome of extreme insulin resistance associated with acanthosis nigricans (Figures 27–1 and 27–2) afflicts either young women with androgenic features as well as insulin receptor mutations or older individuals, mostly women, in whom a circulating immunoglobulin binds to insulin receptors and reduces their affinity to insulin.

Many medications (calcineurin inhibitors, sirolimus, thiazides, β-blockers, corticosteroids, niacin, atypical antipsychotics) are associated with carbohydrate intolerance or frank diabetes. The medications act by decreasing insulin secretion or by increasing insulin resistance or both. Cyclosporine and tacrolimus impair insulin secretion; sirolimus principally increases insulin resistance. These agents contribute to the development of new-onset diabetes after transplantation. Corticosteroids increase insulin resistance but may also have an effect on beta cell function; in a case control study and a large population cohort study, oral corticosteroids doubled the risk for development of diabetes. Thiazide diuretics and β-blockers modestly increase the risk for diabetes. Treating the hypokalemia due to thiazides may reverse the hyperglycemia. Atypical antipsychotics, particularly olanzapine and clozapine, have been associated with increased risk of glucose intolerance. These medications cause weight gain and insulin resistance but may also impair beta cell function; an increase in rates of diabetic ketoacidosis has been reported.

Chronic pancreatitis or subtotal pancreatectomy reduces the number of functioning B cells and can result in a metabolic derangement very similar to that of genetic type 1 diabetes except that a concomitant reduction in pancreatic A cells may reduce glucagon secretion so that relatively lower doses of insulin replacement are needed.

Insulin Resistance Syndrome (Syndrome X; Metabolic Syndrome)

Twenty-five percent of the general nonobese, nondiabetic population has insulin resistance of a magnitude similar to that seen in type 2 diabetes. These insulin-resistant diabetic individuals are at much higher risk for developing type 2 diabetes than insulin-sensitive persons. In addition to diabetes, these individuals have increased risk for elevated plasma triglycerides, lower high-density lipoproteins (HDLs), and higher blood pressure—a cluster of abnormalities termed syndrome X or metabolic syndrome. These associations have now been expanded to include small, dense, low-density lipoprotein (LDL), hyperuricemia, abdominal obesity, prothrombotic state with increased levels of plasminogen activator inhibitor type 1 (PAI-1), and proinflammatory state. These clusters of abnormalities significantly increase the risk of atherosclerotic disease.

It has been postulated that hyperinsulinemia and insulin resistance play a direct role in these metabolic abnormalities, but supportive evidence is inconclusive. Although hyperinsulinemia and hypertension often coexist in whites, that is not the case in blacks or Pima Indians. Moreover, patients with hyperinsulinemia due to insulinoma are not hypertensive, and there is no fall in blood pressure after surgical removal of the insulinoma restores normal insulin levels. The main value of grouping these disorders as a syndrome, however, is to remind clinicians that the therapeutic goals are not only to correct hyperglycemia but also to manage the elevated blood pressure and dyslipidemia that result in increased cerebrovascular and cardiac morbidity and mortality in these patients.

Clinical Findings

The principal clinical features of the two major types of diabetes mellitus are listed for comparison in Table 27–4.
Patients with type 1 diabetes have a characteristic symptom complex. An absolute deficiency of insulin results in accumulation of circulating glucose and fatty acids, with consequent hyperosmolality and hyperketonemia.

Patients with type 2 diabetes may or may not have characteristic features. The presence of obesity or a strongly positive family history for mild diabetes suggests a high risk for the development of type 2 diabetes.

### A. Symptoms and Signs

#### 1. Type 1 diabetes—

- Increased urination is a consequence of osmotic diuresis secondary to sustained hyperglycemia. This results in a loss of glucose as well as free water and electrolytes in the urine. Thirst is a consequence of the hyperosmolar state, as is blurred vision, which often develops as the lenses are exposed to hyperosmolar fluids.
- Weight loss despite normal or increased appetite is a common feature of type 1 when it develops subacutely. The weight loss is initially due to depletion of water, glycogen, and triglycerides; thereafter, reduced muscle mass occurs as amino acids are diverted to form glucose and ketone bodies.
- Lowered plasma volume produces symptoms of postural hypotension. Total body potassium loss and the general catabolism of muscle protein contribute to the weakness.
- Paresthesias may be present at the time of diagnosis, particularly when the onset is subacute. They reflect a temporary dysfunction of peripheral sensory nerves, which clears as insulin replacement restores glycemic levels closer to normal, suggesting neurotoxicity from sustained hyperglycemia.
- When absolute insulin deficiency is of acute onset, the above symptoms develop abruptly. Ketoacidosis exacerbates the dehydration and hyperosmolality by producing anorexia and nausea and vomiting, interfering with oral fluid replacement.
- The patient’s level of consciousness can vary depending on the degree of hyperosmolality. When insulin deficiency develops relatively slowly and sufficient water intake is maintained, patients remain relatively alert and physical findings may be minimal. When vomiting occurs in response to worsening ketoacidosis, dehydration progresses and compensatory mechanisms become inadequate to keep serum osmolality below 320–330 mosm/L. Under these circumstances, stupor or even coma may occur. The fruity breath odor of acetone further suggests the diagnosis of diabetic ketoacidosis.

Hypotension in the recumbent position is a serious prognostic sign. Loss of subcutaneous fat and muscle wasting are features of more slowly developing insulin deficiency. In occasional patients with slow, insidious onset of insulin deficiency, subcutaneous fat may be considerably depleted.

#### 2. Type 2 diabetes—

While increased urination and thirst may be present symptoms in some patients with type 2 diabetes, many other patients have an insidious onset of hyperglycemia and are asymptomatic initially. This is particularly true in obese patients, whose diabetes may be detected only after glycosuria or hyperglycemia is noted during routine laboratory studies. Occasionally, when the disease has been occult for some time, patients with type 2 diabetes may have evidence of neuropathic or cardiovascular complications at the time of presentation. Chronic skin infections are common. Generalized pruritus and symptoms of vaginitis are frequently the initial complaints of women. Diabetes should be suspected in women with chronic candidal vaginovaginitis as well as in those who have delivered large babies (>9 lb, or 4.1 kg) or have had polyhydramnios, preeclampsia, or unexplained fetal losses. Balanoposthitis (inflammation of the foreskin and glans in uncircumcised males) may occur.

Many patients with type 2 diabetes are overweight or obese. Even those who are not significantly obese often have characteristic localization of fat deposits on the upper segment of the body (particularly the abdomen, chest, neck, and face) and relatively less fat on the appendages, which may be quite muscular. This centripetal fat distribution is characterized by a high waist circumference; a waist circumference >40 inches (102 cm) in men and 35 inches (88 cm) in women is associated with an increased risk of diabetes. Some patients may have acanthosis nigricans, which is associated with significant insulin resistance; the skin in the axilla, groin, and back of neck is hyperpigmented and hyperkeratotic (Figures 27-1 and 27-2). Mild hypertension is often present in obese diabetics. Eruptive xanthomas on the flexor surface of the limbs and on the buttocks and lipemia retinalis due to hyperchylomicronemia can occur in patients with uncontrolled type 2 diabetes who also have a familial form of hypertriglyceridemia.

Hyperglycemic hyperosmolar coma can also be present; in these cases, patients are profoundly dehydrated, hypotensive, lethargic or comatose but without Kussmaul respirations.

### B. Laboratory Findings

#### 1. Urinalysis

- **Glucosuria**—A specific and convenient method to detect glucosuria is the paper strip impregnated with glucose oxidase and a chromogen system (Clinistix, Diastix), which is sensitive to as little as 100 mg/dL (5.5 mmol) glucose in urine. Diastix can be directly applied to the urinary
stream, and differing color responses of the indicator strip reflect glucose concentration.

A normal renal threshold for glucose as well as reliable bladder emptying is essential for interpretation. Nondiabetic glycosuria (renal glycosuria) is a benign asymptomatic condition wherein glucose appears in the urine despite a normal amount of glucose in the blood, either basally or during a glucose tolerance test. Its cause may vary from mutations in the SGLT2 gene coding for sodium-glucose transporter 2 (familial renal glycosuria) to one associated with dysfunction of the proximal renal tubule (Fanconi syndrome, chronic kidney disease), or it may merely be a consequence of the increased load of glucose presented to the tubules by the elevated glomerular filtration rate during pregnancy. As many as 50% of pregnant women normally have demonstrable sugar in the urine, especially during the third and fourth months. This sugar is practically always glucose except during the late weeks of pregnancy, when lactose may be present.

**B. Ketonuria—**Qualitative detection of ketone bodies can be accomplished by nitroprusside tests (Acetest or Ketostix). Although these tests do not detect β-hydroxybutyric acid, which lacks a ketone group, the semiquantitative estimation of ketonemia thus obtained is nonetheless usually adequate for clinical purposes. Many laboratories now measure β-hydroxybutyric acid, and there is a meter available (Precision Xtra, Abbott Diabetes Care) for patient use that measures β-hydroxybutyric acid levels in capillary glucose samples. β-Hydroxybutyrate levels > 0.6 mmol/L require evaluation. Patients with levels > 3.0 mmol/L, equivalent to very large urinary ketones, require hospitalization.

### 2. Blood testing procedures

**A. Plasma or serum glucose—**Plasma or serum from venous blood samples has the advantage over whole blood of providing values for glucose that are independent of hematocrit and that reflect the glucose concentration to which body tissues are exposed. Venous samples should be collected in tubes containing sodium fluoride to prevent glycolysis, placed on ice and the plasma separated from cells within 60 minutes. In the absence of fluoride, the rate of disappearance of glucose in presence of blood cells has been reported to be approximately 10 mg/dL/h (0.56 mmol/L). The glucose concentration is 10–15% higher in plasma or serum than in whole blood because structural components of blood cells are absent. A plasma glucose level of 126 mg/dL (7 mmol/L) or higher or on more than one occasion after at least 8 hours of fasting is diagnostic of diabetes mellitus (Table 27–5). Fasting plasma glucose levels of 100–125 mg/dL (5.6–6.9 mmol/L) are associated with increased risk of diabetes (impaired fasting glucose tolerance).

**B. Oral glucose tolerance test—**If the fasting plasma glucose level is < 126 mg/dL (7 mmol/L) when diabetes is nonetheless suspected, then a standardized oral glucose tolerance test may be done (Table 27–5). In order to optimize insulin secretion and effectiveness, especially when patients have been on a low-carbohydrate diet, a minimum of 150–200 g of carbohydrate per day should be included in the diet for 3 days preceding the test. The patient should eat nothing after midnight prior to the test day. On the morning of the test, adults are then given 75 g of glucose in 300 mL of water; children are given 1.75 g of glucose per kilogram of ideal body weight. The glucose load is consumed within 5 minutes. The test should be performed in the morning because there is some diurnal variation in oral glucose tolerance, and patients should not smoke or be active during the test.

Blood samples for plasma glucose are obtained at 0 and 120 minutes after ingestion of glucose. An oral glucose tolerance test is normal if the fasting venous plasma glucose value is < 100 mg/dL (5.6 mmol/L) and the 2-hour value falls below 140 mg/dL (7.8 mmol/L). A fasting value of 126 mg/dL (7 mmol/L) or higher or a 2-hour value of > 200 mg/dL (11.1 mmol/L) is diagnostic of diabetes mellitus. Patients with 2-hour value of 140–199 mg/dL (7.8–11.1 mmol/L) have impaired glucose tolerance. False-positive results may occur in patients who are malnourished, bedridden, or afflicted with an infection or severe emotional stress. Diuretics, oral contraceptives, corticosteroids, excess thyroxine, phenytoin, nicotinic acid, and some psychotropic medications may also cause false-positive results.

**C. Glycated hemoglobin (hemoglobin A1c) measurements—**Hemoglobin becomes glycated by ketoamine reactions between glucose and other sugars and the free amino groups on the α and β chains. Only glycation of the N-terminal valine of the beta chain imparts sufficient negative charge to the hemoglobin molecule to allow separation by charge dependent techniques. These charge separated hemoglobins are collectively referred to as hemoglobin A1c (HbA1c). The major form of HbA1c is hemoglobin A1c (HbA1c) where glucose is the carbohydrate. HbA1c comprises 4–6% of total hemoglobin A1. The remaining HbA1 species contain fructose-1,6 diphosphate (HbA1d); glucose-6-phosphate (HbA1g); and unknown carbohydrate moiety (HbA1n). The hemoglobin A1c fraction is abnormally elevated in diabetic persons with chronic hyperglycemia. Methods for measuring HbA1c include electrophoresis, cation-exchange chromatography, boronate affinity chromatography, and immunoassays. Office-based immunoassays using capillary blood give a result in about 9 minutes.

1 Give 75 g of glucose dissolved in 300 mL of water after an overnight fast in persons who have been receiving at least 150–200 g of carbohydrate daily for 3 days before the test.

2 A fasting plasma glucose ≥ 126 mg/dL (7.0 mmol) or HbA1c of ≥ 6.5% is diagnostic of diabetes if confirmed by repeat testing.
and this allows for nearly immediate feedback to the patients regarding their glycemic control.

Since glycohemoglobins circulate within red blood cells whose life span lasts up to 120 days, they generally reflect the state of glycemia over the preceding 8–12 weeks, thereby providing an improved method of assessing diabetic control. The Hba1c value, however, is weighted to more recent glucose levels (previous month) and this explains why significant changes in HbA1c are observed with short-term (1 month) changes in mean plasma glucose levels. Measurements should be made in patients with either type of diabetes mellitus at 3- to 4-month intervals so that adjustments in therapy can be made if HbA1c is either subnormal or if it is more than 2% above the upper limits of normal for a particular laboratory. In patients monitoring their own blood glucose levels, HbA1c values provide a valuable check on the accuracy of monitoring. In patients who do not monitor their own blood glucose levels, HbA1c values are essential for adjusting therapy. There is a linear relationship between the HbA1c and the average glucose levels in the previous 3 months as determined from continuous glucose monitoring data and from seven-point capillary blood glucose profiles (preprandial, postprandial, and bedtime). Table 27–6 gives the mean capillary glucose values for HbA1c values ranging from 5% to 12%.

The accuracy of HbA1c values can be affected by hemoglobin variants or traits; the effect depends on the specific hemoglobin variant or derivative and the specific assay used. Immunoassays that use an antibody to the glycated amino terminus of β globin do not recognize the terminus of the γ globin of hemoglobin F. Thus, in patients with high levels of hemoglobin F, immunoassays give falsely low values of HbA1c. Cation-exchange chromatography separates hemoglobin species by charge differences. Hemoglobin variants that co-elute with HbA1c can lead to an overestimation of the HbA1c value. Chemically modified derivatives of hemoglobin such as carbamoylation (in end-stage chronic kidney disease) or acetylation (high-dose aspirin therapy) can similarly co-elute with HbA1c by some assay methods. The National Glycohemoglobin Standardization Program website (www.ngsp.org) has information on the impact of frequently encountered hemoglobin variants and traits on the results obtained with the commonly used HbA1c assays.

Any condition that shortens erythrocyte survival or decreases mean erythrocyte age (eg, recovery from acute blood loss, hemolytic anemia) will falsely lower HbA1c irrespective of the assay method used. Alternative methods such as fructosamine (see below) should be considered for these patients. Vitamins C and E are reported to falsely lower test results possibly by inhibiting glycation of hemoglobin.

The ADA has endorsed using the HbA1c as a diagnostic test for diabetes (Table 27–5). A cutoff value of 6.5% was chosen because the risk for retinopathy increases substantially above this value. The advantages of using the HbA1c to diagnose diabetes is that there is no need to fast; it has lower intra-individual variability than the fasting glucose test and the oral glucose tolerance test; and it provides an estimate of glucose control for the preceding 2–3 months. People with HbA1c levels of 5.7–6.4% should be considered at high risk for developing diabetes (prediabetes). The diagnosis should be confirmed with a repeat HbA1c test, unless the patient is symptomatic with plasma glucose levels > 200 mg/dL (11.1 mmol/L). This test is not appropriate to use in populations with high prevalence of hemoglobinopathies or in conditions with increased red cell turnover. Also, the testing should be performed using a National Glycohemoglobin Standardization Program certified method and standardized to the Diabetes Control and Complications Trial assay.

### Table 27–6. Correlations of HbA1c levels with average of capillary glucose measurements (preprandial, postprandial and bedtime) in the previous 3 months.

DCT, Diabetes Complications and Control Trial.

D. **Serum fructosamine**—Serum fructosamine is formed by nonenzymatic glycosylation of serum proteins (predominantly albumin). Since serum albumin has a much shorter half-life than hemoglobin, serum fructosamine generally reflects the state of glycemic control for only the preceding 1–2 weeks. Reductions in serum albumin (eg, nephrotic state or hepatic disease) will lower the serum fructosamine value. When abnormal hemoglobins or hemolytic states affect the interpretation of glycohemoglobin or when a narrower time frame is required, such as for ascertaining glycemic control at the time of conception in a diabetic woman who has recently become pregnant, serum fructosamine assays offer some advantage. Normal values vary in relation to the serum albumin concentration and are 200–285 mcmol/L when the serum albumin level is 5 g/dL. HbA1c values and serum fructosamine are highly correlated. The following relationship between serum fructosamine levels and HbA1c has been reported based on linear regression analysis:

$$
\text{HbA1c} = 0.017 \times \text{serum fructosamine level (mcmol/L)} + 1.61
$$

Thus, serum fructosamine levels of 317, 375, and 435 mcmol/L are equivalent to HbA1c values of 7%, 8%, and 9%.
E. Self-monitoring of blood glucose—Capillary blood glucose measurements performed by patients themselves, as outpatients, are extremely useful. In type 1 patients in whom “tight” metabolic control is attempted, they are indispensable. There are several paper strip (glucose oxidase, glucose dehydrogenase, or hexokinase) methods for measuring glucose on capillary blood samples. A反射ance photometer or an amperometric system is then used to measure the reaction that takes place on the reagent strip. A large number of blood glucose meters are now available. All are accurate, but they vary with regard to speed, convenience, size of blood samples required, reporting capability, and cost. Popular models include those manufactured by LifeScan (One Touch), Bayer Corporation (Breeze, Contour), Roche Diagnostics (Accu-Chek), and Abbott Laboratories (Precision, FreeStyle). These blood glucose meters are relatively inexpensive, ranging from $50 to $100 each. Test strips remain a major expense, costing $5.50 to $7.50 apiece. Each glucose meter also comes with a lancet device and disposable 26- to 33-gauge lancets. The accuracy of data obtained by home glucose monitoring does require education of the patient in sampling and measuring procedures as well as in properly calibrating the instruments.

The clinician should be aware of the limitations of the self-monitoring glucose systems. First, some older meters require input of a code for each batch of strips; failure to enter the code can result in misleading results. Many of the newer meters no longer require this step. Second, increases or decreases in hematocrit can decrease or increase the measured glucose values. The mechanism underlying this effect is not known but presumably it is due to the impact of red cells on the diffusion of plasma into the reagent layer. Third, the meters and the test strips are calibrated over the glucose concentrations ranging from 60 mg/dL (3.3 mmol/L) to 160 mg/dL (8.9 mmol/L) and the accuracy is not as good for higher and lower glucose levels. When the glucose is < 60 mg/dL (3.3 mmol/L), the difference between the meter and the laboratory value may be as much as 20%. Fourth, glucose oxidase–based amperometric systems underestimate glucose levels in the presence of high oxygen tension. This may be important in the critically ill who are receiving supplemental oxygen; under these circumstances, a glucose dehydrogenase–based system may be preferable. Fifth, glucose-dehydrogenase pyrroloquinoline quinone (GDH-PQQ) systems may report falsely high glucose levels in patients who are receiving parenteral products containing nonglucose sugars such as maltose, galactose, or xylose or their metabolites. Patients have been given falsely high glucose values resulting in life-threatening hypoglycemia.

Sixth, some meters have been approved for measuring glucose in blood samples obtained at alternative sites such as the forearm and thigh. There is, however, a 5- to 20-minute lag in the glucose response on the arm with respect to the glucose response on the finger. Forearm blood glucose measurements could therefore result in a delay in detection of rapidly developing hypoglycemia.

F. Continuous glucose monitoring systems—A number of continuous glucose monitoring systems are available for clinical use. The systems manufactured by Medtronic Minimed, DexCom systems, and Abbott Diagnostics (outside United States), involve inserting a subcutaneous sensor (rather like an insulin pump cannula) that measures glucose concentrations in the interstitial fluid for 3–7 days. The data are transmitted to a separate pager-like device with a screen. The MiniMed system also has the option to wirelessly transmit the data to the screen of their insulin pump. The systems allow the patient to set “alerts” for low and high glucose values and rate of change of glucose levels. Patients still have to calibrate the devices with periodic fingerstick glucose levels, and since there are concerns regarding reliability, it is still necessary to confirm the displayed glucose level with a fingerstick glucose before making interventions such as injecting extra insulin or eating extra carbohydrates. A 6-month randomized controlled study of type 1 patients showed that adults (25 years and older) using these systems had improved glycemic control without an increase in the incidence of hypoglycemia. A randomized controlled study of continuous glucose monitoring during pregnancy showed improved glycemic control in the third trimester, lower birth weight, and reduced risk of macrosomia. The individual glucose values are not that critical—what matters is the direction and the rate at which the glucose is changing, allowing the user to take corrective action. The wearer also gains insight into the way particular foods and activities affect their glucose levels. The other main benefit is the low glucose alert warning. The MiniMed insulin pump marketed in Europe can be programmed to automatically suspend insulin delivery for 2 hours when the glucose levels on the continuous glucose monitoring device falls to a preset level. Increasingly, these systems are being covered by insurance. The initial cost is about $800 to $1000, and the sensor, which has to be changed every 3 to 7 days, costs $35 to $60. This adds up to an out-of-pocket expense of about $4000 annually.

There is great interest in using the data obtained from these continuous glucose monitoring systems to automatically deliver insulin by continuous subcutaneous insulin infusion pump. Algorithms have been devised to link continuous glucose monitoring to insulin delivery and preliminary clinical studies appear promising.

3. Lipoprotein abnormalities in diabetes—Circulating lipoproteins are just as dependent on insulin as is the plasma glucose. In type 1 diabetes, moderately deficient control of hyperglycemia is associated with only a slight elevation of LDL cholesterol and serum triglycerides and little if any change in HDL cholesterol. Once the hyperglycemia is corrected, lipoprotein levels are generally normal. However, in patients with type 2 diabetes, a distinct “diabetic dyslipidemia” is characteristic of the insulin resistance syndrome. Its features are a high serum triglyceride level (300–400 mg/dL [3.4–4.5 mmol/L]), a low HDL cholesterol (< 30 mg/dL [0.8 mmol/L]), and a qualitative change in LDL particles, producing a smaller dense particle whose membrane carries supranormal amounts of free cholesterol. These smaller dense LDL particles are more susceptible to oxidation, which renders them more atherogenic. Since a low HDL cholesterol is a major feature predisposing to macrovascular disease, the term “dyslipidemia” has preempted the term “hyperlipidemia,” which mainly denoted the elevated triglycerides. Measures designed to correct the obesity and
hyperglycemia, such as exercise, diet, and hypoglycemic therapy, are the treatment of choice for diabetic dyslipidemia, and in occasional patients in whom normal weight was achieved, all features of the lipoprotein abnormalities cleared. Since primary disorders of lipid metabolism may coexist with diabetes, persistence of lipid abnormalities after restoration of normal weight and blood glucose should prompt a diagnostic workup and possible pharmacotherapy of the lipid disorder. Chapter 28 discusses these matters in detail.

Pickup JC et al. Glycaemic control in type 1 diabetes during real time continuous glucose monitoring compared with self monitoring of blood glucose: meta-analysis of randomised controlled trials using individual patient data. BMJ. 2011 Jul 7;343:d3805. [PMID: 21737469]

Clinical Trials in Diabetes

Findings of the Diabetes Complications and Control Trial (DCCT) and of the United Kingdom Prospective Diabetes Study (UKPDS), have confirmed the beneficial effects of improved glycemic control in both type 1 and type 2 diabetes, respectively (see below). In addition, with increased understanding of the pathophysiology of both type 1 and type 2 diabetes, large prospective studies—Diabetes Prevention Trial 1 (DPT-1) and the Diabetes Prevention Program (DPP)—have been performed in attempts to prevent onset of these disorders (see below).

A. Clinical Trials in Type 1 Diabetes

1. Diabetes Prevention Trial-1—This multicenter study sponsored by the National Institutes of Health was designed to determine whether the development of type 1 diabetes mellitus could be prevented or delayed by immune intervention therapy. Daily low-dose insulin injections were administered for up to 8 years in first-degree relatives of type 1 diabetic patients who were selected as being at high risk for development of type 1 diabetes because of detectable islet cell antibodies and reduced early-insulin release. Unfortunately, this immune intervention failed to affect the onset of type 1 diabetes compared with a randomized untreated group. A related study using oral insulin in lower risk first-degree relatives who have islet cell antibodies but whose early insulin release remains intact also failed to show an effect on the onset of type 1 diabetes. After an average of 4.3 years of observation, type 1 diabetes developed in about 35% of persons in both the oral insulin and the placebo groups.

2. The Diabetes Control and Complications Trial—This long-term therapeutic study involving 1441 patients with type 1 diabetes mellitus reported that “near” normalization of blood glucose resulted in a delay in the onset and a major slowing of the progression of established microvascular and neuropathic complications of diabetes during a follow-up period of up to 10 years. Multiple insulin injections (66%) or insulin pumps (34%) were used in the intensively treated group, who were trained to modify their therapy in response to frequent glucose monitoring. The conventionally treated groups used no more than two insulin injections, and clinical well-being was the goal with no attempt to modify management based on HbA1c determinations or the glucose results. In half of the patients, a mean hemoglobin A1c of 7.2% (normal; <6%) and a mean blood glucose of 155 mg/dL (8.6 mmol/L) were achieved using intensive therapy, while in the conventionally treated group HbA1c averaged 8.9% with an average blood glucose of 225 mg/dL (12.5 mmol/L). Over the study period, which averaged 7 years, there was an approximately 60% reduction in risk between the two groups in regard to diabetic retinopathy, nephropathy, and neuropathy. The intensively treated group also had a nonsignificant reduction in the risk of macrovascular disease of 41% (95% CI, –10 to 68). Intensively treated patients had a threefold greater risk of serious hypoglycemia as well as a greater tendency toward weight gain. However, there were no deaths definitely attributable to hypoglycemia in any persons in the DCCT study, and no evidence of posthypoglycemic cognitive damage was detected.

Subjects participating in the DCCT study were subsequently enrolled in a follow-up observational study, the Epidemiology of Diabetes Interventions and Complications (EDIC) study. Even though the between-group differences in mean HbA1c, narrowed over 4 years, the group assigned to intensive therapy had a lower risk of retinopathy at 4 years, microalbuminuria at 7 to 8 years, and impaired glomerular filtration rate (< 60 mL/min/1.73 m2) at 22 years of continued study follow-up. Moreover, by the end of the 11-year follow-up period, the intensive therapy group had significantly reduced their risk of any cardiovascular disease events by 42% (95% CI, 9% to 23%; P = 0.02). Thus, it seems that the benefits of good glucose control persist even if control deteriorates at a later date.

The general consensus of the ADA is that intensive insulin therapy associated with comprehensive self-management training should become standard therapy in patients with type 1 diabetes mellitus after the age of puberty. Exceptions include those with advanced chronic kidney disease and the elderly, since in these groups the detrimental risks of hypoglycemia outweigh the benefits of tight glycemic control.

3. Immune intervention trials in new-onset type 1 diabetes—At the time of diagnosis of type 1 diabetes, patients still have significant B cell function. This explains
B. Clinical Trials in Type 2 Diabetes

1. The Diabetes Prevention Program—This study was aimed at discovering whether treatment with either diet and exercise or metformin could prevent the onset of type 2 diabetes in people with impaired glucose tolerance; 3234 overweight men and women aged 25–85 years with impaired glucose tolerance participated in the study. Intervention with a low-fat diet and 150 minutes of moderate exercise (equivalent to a brisk walk) per week reduced the risk of progression to type 2 diabetes by 71% compared with a matched control group. Participants taking 850 mg of metformin twice a day reduced their risk of developing type 2 diabetes by 31%, but this intervention was relatively ineffective in those who were either less obese or in the older age group.

With the demonstration that intervention can be successful in preventing progression to diabetes in these subjects, a recommendation has been made to change the terminology from the less comprehensible “impaired glucose tolerance” to “prediabetes.” The latter is a term that the public can better understand and thus respond to by implementing healthier diet and exercise habits.

2. Kumamoto study—The Kumamoto study involved a relatively small number of patients with type 2 diabetes (n = 110) who were nonobese and only slightly insulin-resistant, requiring < 30 units of insulin per day for intensive therapy. Over a 6-year period, it was shown that intensive insulin therapy, achieving a mean HbA1c of 7.1%, significantly reduced microvascular end points compared with conventional insulin therapy achieving a mean HbA1c of 9.4%. Cardiovascular events were neither worsened nor improved by intensive therapy, and weight changes were likewise not influenced by either form of treatment.

3. The United Kingdom Prospective Diabetes Study—This multicenter study was designed to establish, in type 2 diabetic patients, whether the risk of macrovascular or microvascular complications could be reduced by intensive blood glucose control with oral hypoglycemic agents or insulin and whether any particular therapy was of advantage. A total of 3867 patients aged 25–65 years with newly diagnosed diabetes were recruited between 1977 and 1991, and studied over 10 years. The median age at baseline was 54 years; 44% were overweight (>120% over ideal weight); and baseline HbA1c was 9.1%. Therapies were randomized to include a control group on diet alone and separate groups intensively treated with either insulin or sulfonylurea (chlorpropamide, glyburide, or glipizide). Metformin was included as a randomization option in a subgroup of 342 overweight or obese patients, and much later in the study an additional subgroup of both normal-weight and overweight patients who were responding unsatisfactorily to sulfonylurea therapy were randomized to either continue on their sulfonylurea therapy alone or to have metformin combined with it. In 1987, an additional modification was made to evaluate whether tight control of blood pressure with stepwise antihypertensive therapy would prevent macrovascular and microvascular complications in 758 hypertensive patients among this UKPDS population compared with 390 of them whose blood pressure was treated less intensively. The tight control group was randomly assigned to treatment with either an angiotensin-converting enzyme (ACE) inhibitor (captopril) or a β-blocker (atenolol). Both medications were stepped up to maximum dosages of 100 mg/d and then, if blood pressure remained higher than the target level of <150/85 mm Hg, more medications were added in the following stepwise sequence: a diuretic, slow-release nifedipine, methyldopa, and prazosin—until the target level of tight control was achieved. In the control group, hypertension was conventionally treated to achieve target levels <180/105 mm Hg, but these patients were not prescribed either ACE inhibitors or β-blockers.

Intensive treatment with either sulfonylureas, metformin, combinations of those two, or insulin achieved...
The data from the UKPDS and this study provide support for guidelines recommending vigorous treatment of mean HbA1c levels of 7%. This level of glycemic control decreased the risk of microvascular complications (retinopathy and nephropathy) in comparison with conventional therapy (mostly diet alone), which achieved mean levels of HbA1c of 7.9%. Weight gain occurred in intensively treated patients except when metformin was used as monotherapy. No cardiovascular benefit and no adverse cardiovascular outcomes were noted regardless of the therapeutic agent. Hypoglycemic reactions occurred in the intensive treatment groups, but only one death from hypoglycemia was documented during 27,000 patient-years of intensive therapy.

When therapeutic subgroups were analyzed, some unexpected and paradoxical results were noted. Among the obese patients, intensive treatment with insulin or sulfonylureas did not reduce microvascular complications compared with diet therapy alone. This was in contrast to the significant benefit of intensive therapy with these medications in the total group. Furthermore, intensive therapy with metformin was more beneficial in the overweight or obese persons than diet alone with regard to fewer myocardial infarctions, strokes, and diabetes-related deaths, but there was no significant reduction by metformin of diabetic microvascular complications as compared with the diet group. Moreover, in the subgroup of obese and nonobese patients in whom metformin was added to sulfonylurea failures, rather than showing a benefit, there was a 96% increase in diabetes-related deaths compared with the matched cohort of patients with unsatisfactory glycemic control on sulfonylureas who remained on their sulfonylurea therapy. Chlorpropamide also came out poorly on subgroup analysis in that those receiving it as intensive therapy did less well regarding progression to retinopathy than those conventionally treated with diet.

 Tight control of blood pressure (median value 144/82 mm Hg vs 154/87 mm Hg) substantially reduced the risk of microvascular disease and stroke but not myocardial infarction. In fact, reducing blood pressure by this amount had substantially greater impact on microvascular outcomes than that achieved by lowering HbA1c from 7.9% to 7%. An epidemiologic analysis of the UKPDS data did show that every 10 mm Hg decrease in updated mean systolic blood pressure was associated with 11% reduction in risk for myocardial infarction. More than half of the patients needed two or more medications for adequate therapy of their hypertension, and there was no demonstrable advantage of ACE inhibitor therapy over therapy with β-blockers with regard to diabetes end points. Use of a calcium channel blocker added to both treatment groups appeared to be safe over the long term in this diabetic population despite some controversy in the literature about its safety in diabetics.

Like the DCCT trialists, the UKPDS researchers performed post-trial monitoring to determine whether there were long-term benefits of having been in the intensively treated glucose and blood pressure arms of the study. The between-group differences in HbA1c were lost within the first year of follow-up, but the reduced risk (24%, \( P = 0.001 \)) of development or progression of microvascular complications in the intensively treated group persisted for 10 years. The intensively treated group also had significantly reduced risk of myocardial infarction (15%, \( P = 0.01 \)) and death from any cause (13%, \( P = 0.007 \)) during the follow-up period. The subgroup of overweight or obese subjects who were initially randomized to metformin therapy showed sustained reduction in risk of myocardial infarction and death from any cause in the follow-up period. The between-group blood pressure differences disappeared within 2 years of the end of the trial. Unlike the sustained benefits seen with glucose control, there were no sustained benefits from having been in the more tightly controlled blood pressure group. Both blood pressure groups were at similar risk for microvascular events and diabetes-related end points during the follow-up period.

Thus, the follow-up of the UKPDS type 2 diabetes cohort showed that, as in type 1 diabetes, the benefits of good glucose control persist even if control deteriorates at a later date. Blood pressure benefits, however, last only as long as the blood pressure is well controlled.

**4. The Steno-2 study**—The Steno-2 study was designed in 1990 to validate the efficacy of targeting multiple concomitant risk factors for both microvascular and macrovascular disorders in type 2 diabetes. A prospective, randomized, open, blinded end point design was used where 160 patients with type 2 diabetes and microalbuminuria were assigned to conventional therapy with their general practitioner or to intensive care at the Steno Diabetes Center. The intensively treated group had step-wise introduction of lifestyle and pharmacologic interventions aimed at keeping glycated hemoglobin < 6.5%, blood pressure < 130/80 mm Hg; total cholesterol < 175 mg/dL (4.5 mmol/L), and triglycerides < 150 mg/dL (1.7 mmol/L). All the intensively treated group received ACE inhibitors and if intolerant, an angiotensin II-receptor blocker. The lifestyle component of intensive intervention included reduction in dietary fat intake to < 30% of total calories; smoking cessation program; light to moderate exercise; daily vitamin-mineral supplement of vitamin C, E, and chromium picolinate. Initially, aspirin was only given as secondary prevention to patients with a history of ischemic cardiovascular disease; later, all patients received aspirin. After a mean follow-up of 7.8 years, cardiovascular events (eg, myocardial infarction, angioplasties, coronary bypass grafts, strokes, amputations, vascular surgical interventions) developed in 44% of patients in the conventional arm and only in 24% in the intensive multifactorial arm—about a 50% reduction. Rates of nephropathy, retinopathy, and autonomic neuropathy were also lower in the multifactorial intervention arm by 62% and 63%, respectively.

The persons who participated in this trial were subsequently enrolled in an observational follow-up study for an average of 5.5 years. Even though the significant differences in glycemic control and levels of risk factors of cardiovascular disease between the groups had disappeared by the end of the follow-up period, the intervention group continued to have a lower risk of retinal photocoagulation, renal failure, cardiovascular end points, and cardiovascular mortality.
concomitant microvascular and cardiovascular risk factors in patients with type 2 diabetes.

5. ACCORD, ADVANCE, and VADT studies—The ACCORD study was a randomized controlled study designed to determine whether normal HbA1c levels would reduce the risk of cardiovascular events in middle-aged or older individuals with type 2 diabetes. About 35% of the 10,251 recruited subjects had established cardiovascular disease at study entry. The intensive arm of the study was discontinued after 3.5 years of follow-up because of more unexplained deaths in the intensive arm when compared with the control arm (22%, \( P = .020 \)). Analysis of the data at time of discontinuation showed that the intensively treated group (mean HbA1c 6.4%) had a 10% reduction in cardiovascular event rate compared with the standard treated group (mean HbA1c 7.5%), but this difference was not statistically significant.

The ADVANCE trial randomly assigned 11,140 patients with type 2 diabetes to standard or intensive glucose control. The primary outcomes were major macrovascular cardiovascular events (nonfatal myocardial infarction or stroke or death from cardiovascular causes) or microvascular events. Overall, one-third (32%) of the subjects had established cardiovascular disease at study entry. After a median follow-up of 5 years, there was a nonsignificant reduction (6%) in major macrovascular event rate in the intensively treated group (mean HbA1c 6.5%) compared with the standard therapy group (HbA1c 7.3%).

The Veteran Administration Diabetes Trial (VADT) randomly assigned 1791 patients from age 50 to 69 years with type 2 diabetes to standard or intensive glucose control. Overall, 97% of the subjects were men. The primary outcome was a composite of myocardial infarction, death from cardiovascular causes, congestive heart failure, vascular surgery, inoperable coronary artery disease, and amputation for gangrene. All the patients had optimized blood pressure and lipid levels. After a median follow-up of 5.6 years, there was no significant difference in the primary outcome in the intensively treated group (HbA1c 6.9%) compared with the standard therapy (HbA1c 8.4%). Within this larger study, there was an embedded study evaluating the impact of the intensive therapy on patients who were subcategorized as having low, moderate, and high coronary calcium scores on CT scans. Patients with low coronary calcium score showed a reduced number of cardiovascular events with intensive therapy.

Thus, the ACCORD, ADVANCE, and VADT results do not provide support for the hypothesis that near-normal glucose control in patients with type 2 diabetes will reduce cardiovascular events. It is, however, important not to overinterpret the results of these three studies. The results do not exclude the possibility that cardiovascular benefits might accrue with longer duration of near-normal glucose control. In the UKPDS, risk reductions for myocardial infarction and death from any cause were only observed during 10 years of post-trial follow-up. Specific subgroups of type 2 diabetic patients may also have different outcomes. The ACCORD, ADVANCE, and VADT studies recruited patients who had diabetes for 8–10 years and one-third of them already had established cardiovascular disease. Patients in the UKPDS, in contrast, had newly diagnosed diabetes and only 7.5% had a history of macrovascular disease. It is possible that the benefits of tight glycemic control on macrovascular events are attenuated in patients with longer duration of diabetes or with established vascular disease. Specific therapies used to lower glucose may also affect cardiovascular event rate or mortality. Severe hypoglycemia occurred more frequently in the intensively treated groups of the ACCORD, ADVANCE, and VADT studies; the ACCORD investigators were not able to exclude undiagnosed hypoglycemia as a potential cause for the increased death rate in the intensive treatment group.

A formal meta-analysis performed of the raw trial data from the ACCORD, ADVANCE, VADT, and UKPDS studies found that allocation to more intensive glucose control reduced the risk of myocardial infarction by 15% (hazard ratio 0.85, 95% CI 0.76–0.94). This benefit occurred in patients who did not have preexisting macrovascular disease.

#### Treatment Regimens

### A. Diet

A well-balanced, nutritious diet remains a fundamental element of therapy. The American Diabetes Association (ADA) recommends about 45–65% of total daily calories in the form of carbohydrates; 25–35% in the form of fat (of which < 7% are from saturated fat), and 10–35% in the form of protein. In patients with type 2 diabetes, limiting the carbohydrate intake and substituting some of the calories with monounsaturated fats, such as olive oil, rapeseed (canola) oil, or the oils in nuts and avocados, can lower triglycerides and increase HDL cholesterol. In addition, in those patients
with obesity and type 2 diabetes, weight reduction by caloric restriction is an important goal of the diet. Patients with type 1 diabetes or type 2 diabetes who take insulin should be taught “carbohydrate counting,” so they can administer their insulin bolus for each meal based on its carbohydrate content. In obese individuals with diabetes, an additional goal is weight reduction by caloric restriction (see Chapter 29).

The current recommendations for both types of diabetest continue to limit cholesterol to 300 mg daily, and individuals with LDL cholesterol more than 100 mg/dL (2.6 mmol/L) should limit dietary cholesterol to 200 mg daily. High protein intake may cause progression of kidney disease in patients with diabetic nephropathy; for these individuals, a reduction in protein intake to 0.8 kg/day (or about 10% of total calories daily) is recommended.

Exchange lists for meal planning can be obtained from the American Diabetes Association and its affiliate associations or from the American Dietetic Association (http://www.eatright.org), 216 W. Jackson Blvd., Chicago, IL 60606 (312-899-0040).

1. **Dietary fiber**—Plant components such as cellulose, gum, and pectin are indigestible by humans and are termed dietary “fiber.” Insoluble fibers such as cellulose or hemicellulose, as found in bran, tend to increase intestinal transit and may have beneficial effects on colonic function. In contrast, soluble fibers such as gums and pectins, as found in beans, oatmeal, or apple skin, tend to retard nutrient absorption rates so that glucose absorption is slower and hyperglycemia may be slightly diminished. Although its recommendations do not include insoluble fiber supplements such as added bran, the ADA recommends food such as oatmeal, cereals, and beans with relatively high soluble fiber content as staple components of the diet in diabetics. High soluble fiber content in the diet may also have a favorable effect on blood cholesterol levels.

2. **Glycemic index**—The glycemic index of a carbohydrate containing food is determined by comparing the glucose excursions after consuming 50 g of test food with glucose excursions after consuming 50 g of reference food (white bread):

\[
\text{glycemic index} = \frac{\text{Blood glucose area under the curve (3h) for test food}}{\text{Blood glucose area under the curve (3h) for reference food}} \times 100
\]

Eating low glycemic index foods results in lower glucose levels after meals. Low glycemic index foods have values of 55 or less and include many fruits, vegetables, grainy breads, pasta, and legumes. High glycemic index foods have values of 70 or greater and include baked potato, white bread, and white rice. Glycemic index is lowered by presence of fats and protein when food is consumed in a mixed meal. Even though it may not be possible to accurately predict the glycemic index of a particular food in the context of a meal, it is reasonable to choose foods with low glycemic index.

### 3. Artificial and other sweeteners

- Aspartame (Nutra Sweet) consists of two major amino acids, aspartic acid and phenylalanine, which combine to produce a sweetener 180 times as sweet as sucrose. A major limitation is that it is not heat stable, so it cannot be used in cooking. Saccharin (Sweet ’N Low), Sucralose (Splenda), Acesulfame potassium (Sweet One), and rebaiana (Truvia) are other “artificial” sweeteners that can be used in cooking and baking.

Fructose represents a “natural” sugar substance that is a highly effective sweetener, induces only slight increases in plasma glucose levels, and does not require insulin for its metabolism. However, because of potential adverse effects of large amounts of fructose on raising serum cholesterol, triglycerides, and LDL cholesterol, it does not have any advantage as a sweetening agent in the diabetic diet. This does not preclude, however, ingestion of fructose-containing fruits and vegetables or fructose-sweetened foods in moderation.

Sugar alcohols, also known as polyols or polyalcohols, are commonly used as sweeteners and bulking agents. They occur naturally in a variety of fruits and vegetables but are also commercially made from sucrose, glucose, and starch. Examples are sorbitol, xylitol, mannitol, lactitol, isomalt, maltitol, and hydrogenated starch hydrolysates (HSH). They are not as easily absorbed as sugar, so they do not raise blood glucose levels as much. Therefore, sugar alcohols are often used in food products that are labeled as “sugar free,” such as chewing gum, lozenges, hard candy, and sugar-free ice cream. However, if consumed in large quantities, they will raise blood glucose and can cause bloating and diarrhea.

### B. Medications for Treating Hyperglycemia

The medications for treating type 2 diabetes (Table 27–7) fall into several categories: (1) Medications that primarily stimulate insulin secretion by binding to the sulfonylurea receptor: Sulfonylureas remain the most widely prescribed medications for treating hyperglycemia. The meglitinide analog repaglinide and the D-phenylalanine derivative nateglinide also bind the sulfonylurea receptor and stimulate insulin secretion. (2) Medications that primarily lower glucose levels by their actions on the liver, muscle, and adipose tissue: Metformin works in the liver. The thiazolidinediones appear to have their main effect on skeletal muscle and adipose tissue. (3) Medications that principally affect absorption of glucose: The α-glucosidase inhibitors acarbose and miglitol are such currently available therapies. (4) Medications that mimic incretin effect or prolong incretin action: Glucagon-like peptide 1 (GLP1) receptor agonists and DPP 1V inhibitors fall into this category. (5) Other: Pramlintide lowers glucose by suppressing glucagon and slowing gastric emptying.

#### A. Sulfonylureas—The primary mechanism of action of the sulfonylureas is to stimulate insulin release from pancreatic B cells. Specific receptors on the surface of pancreatic B cells bind sulfonylureas in the rank order of their

(continued)
insulinotropic potency (glyburide with the greatest affinity and tolbutamide with the least affinity). It has been shown that activation of these receptors closes potassium channels, resulting in depolarization of the B cell. This depolarized state permits calcium to enter the cell and actively promote insulin release.

Sulfonylureas are not indicated for use in type 1 diabetes patients since these medications require functioning pancreatic B cells to produce their effect on blood glucose. These medications are used in patients with type 2 diabetes, in whom acute administration improves the early phase of insulin release that is refractory to acute glucose stimulation. Sulfonylureas are metabolized by the liver and apart from acetohexamide, whose metabolite is more active than the parent compound, the metabolites of all the other sulfonylureas are weakly active or inactive. The metabolites are excreted by the kidney and, in the case of the second-generation sulfonylureas, partly excreted in the bile. Sulfonylureas are generally contraindicated in patients with severe liver or kidney impairment. Idiosyncratic reactions are rare, with skin rashes or hematologic toxicity (leukopenia, thrombocytopenia) occurring in < 0.1% of users.

1Restricted Distribution Program in place in the United States.

Only one or two tablets daily with a maximum dose of 3000 mg/d. Because of its short duration of action, which is independent of kidney function, tolbutamide is relatively safe to use in renal impairment. Prolonged hypoglycemia has been reported rarely with tolbutamide, mostly in patients receiving certain antibacterial sulfonamides (sulfisoxazole), phenylbutazone for arthralgias, or the oral azole antifungal medications to treat candidiasis. These medications apparently compete with tolbutamide for oxidative enzyme systems in the liver, resulting in maintenance of high levels of unmetabolized, active sulfonylurea in the circulation.

Tolazamide, acetohexamide, and chlorpropamide are rarely used. Chlorpropamide has a prolonged biologic effect, and severe hypoglycemia can occur especially in the elderly as their renal clearance declines with aging. Its other side effects include alcohol-induced flushing and hyponatremia due to its effect on vasopressin secretion and action.

**Second-generation sulfonylureas (glyburide, glipizide, gliclazide, glimepiride)**—Glyburide, glipizide, gliclazide, and glimepiride are 100–200 times more potent than tolbutamide. These medications should be used with caution in patients with cardiovascular disease or in elderly patients, in whom prolonged hypoglycemia would be especially dangerous.

Glyburide is available in 1.25 mg, 2.5 mg, and 5 mg tablets. The usual starting dose is 2.5 mg/d, and the average maintenance dose is 5–10 mg/d given as a single morning dose; maintenance doses higher than 20 mg/d are not recommended. Some reports suggest that 10 mg is a maximum daily use.
therapeutic dose, with 15–20 mg having no additional benefit in poor responders and doses over 20 mg actually worsening hyperglycemia. Glyburide is metabolized in the liver into products with hypoglycemic activity, which probably explains why assays specific for the unmetabolized compound suggest a plasma half-life of only 1–2 hours, yet the biologic effects of glyburide are clearly persistent 24 hours after a single morning dose in diabetic patients. Glyburide is unique among sulfonylureas in that it not only binds to the pancreatic B cell membrane sulfonylurea receptor but also becomes sequestered within the B cell. This may also contribute to its prolonged biologic effect despite its relatively short circulating half-life. A “Press Tab” formulation of “micronized” glyburide—easy to divide in half with slight pressure if necessary—is available in tablet sizes of 1.5 mg, 3 mg, and 6 mg.

Glyburide has few adverse effects other than its potential for causing hypoglycemia, which at times can be prolonged. Flushing has rarely been reported after ethanol ingestion. It does not cause water retention, as chlorpropamide does, but rather slightly enhances free water clearance. Glyburide should not be used in patients with liver failure and renal failure because of the risk of hypoglycemia. Elderly patients are at particular risk for hypoglycemia even with relatively small daily doses.

Glipizide is available in 5 and 10 mg tablets. For maximum effect in reducing postprandial hyperglycemia, this agent should be ingested 30 minutes before meals, since rapid absorption is delayed when the medication is taken with food. The recommended starting dose is 5 mg/d, with up to 15 mg/d given as a single daily dose before breakfast. When higher daily doses are required, they should be divided and given before meals. The maximum dose recommended by the manufacturer is 40 mg/d, although doses above 10–15 mg probably provide little additional benefit in poor responders and may even be less effective than smaller doses.

At least 90% of glipizide is metabolized in the liver to inactive products, and 10% is excreted unchanged in the urine. Glipizide therapy should therefore not be used in patients with liver failure. Because of its lower potency and shorter duration of action, it is preferable to glyburide in elderly patients. Glipizide has also been marketed as Glucotrol-XL in 2.5, 5, and 10 mg tablets. It provides extended release during transit through the gastrointestinal tract with greater effectiveness in lowering prebreakfast hyperglycemia than the shorter-duration immediate-release standard glipizide tablets. However, this formulation appears to have sacrificed its lower propensity for severe hypoglycemia compared with longer-acting glyburide without showing any demonstrable therapeutic advantages over glyburide.

Gliclazide (not available in the United States) is another intermediate duration sulfonylurea with a duration of action of about 12 hours. It is available as 80 mg tablets. The recommended starting dose is 40–80 mg/d with a maximum dose of 320 mg. Doses of 160 mg and above are given as divided doses before breakfast and dinner. The medication is metabolized by the liver; the metabolites and conjugates have no hypoglycemic effect. An extended release preparation is available.

Glimepiride is available as 1, 2 and 4 mg tablets. It has a long duration of effect with a half-life of 5 hours allowing once or twice daily dosing. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound. A single daily dose of 1 mg/d has been shown to be effective, and the maximal recommended dose is 8 mg. It is completely metabolized by the liver to relatively inactive metabolic products.

B. Meglitinide analogs—Repaglinide is structurally similar to glyburide but lacks the sulfonic acid-urea moiety. It acts by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. It is rapidly absorbed from the intestine and then undergoes complete metabolism in the liver to inactive biliary products, giving it a plasma half-life of < 1 hour. The medication therefore causes a brief but rapid pulse of insulin. The starting dose is 0.5 mg three times a day 15 minutes before each meal. The dose can be titrated to a maximal daily dose of 16 mg.

Glyburide has few adverse effects other than its potential for causing hypoglycemia, which at times can be prolonged. Flushing has rarely been reported after ethanol ingestion. It does not cause water retention, as chlorpropamide does, but rather slightly enhances free water clearance. Glyburide should not be used in patients with liver failure and renal failure because of the risk of hypoglycemia. Elderly patients are at particular risk for hypoglycemia even with relatively small daily doses.

Glipizide is available in 5 and 10 mg tablets. For maximum effect in reducing postprandial hyperglycemia, this agent should be ingested 30 minutes before meals, since rapid absorption is delayed when the medication is taken with food. The recommended starting dose is 5 mg/d, with up to 15 mg/d given as a single daily dose before breakfast. When higher daily doses are required, they should be divided and given before meals. The maximum dose recommended by the manufacturer is 40 mg/d, although doses above 10–15 mg probably provide little additional benefit in poor responders and may even be less effective than smaller doses.

At least 90% of glipizide is metabolized in the liver to inactive products, and 10% is excreted unchanged in the urine. Glipizide therapy should therefore not be used in patients with liver failure. Because of its lower potency and shorter duration of action, it is preferable to glyburide in elderly patients. Glipizide has also been marketed as Glucotrol-XL in 2.5, 5, and 10 mg tablets. It provides extended release during transit through the gastrointestinal tract with greater effectiveness in lowering prebreakfast hyperglycemia than the shorter-duration immediate-release standard glipizide tablets. However, this formulation appears to have sacrificed its lower propensity for severe hypoglycemia compared with longer-acting glyburide without showing any demonstrable therapeutic advantages over glyburide.

Gliclazide (not available in the United States) is another intermediate duration sulfonylurea with a duration of action of about 12 hours. It is available as 80 mg tablets. The recommended starting dose is 40–80 mg/d with a maximum dose of 320 mg. Doses of 160 mg and above are given as divided doses before breakfast and dinner. The medication is metabolized by the liver; the metabolites and conjugates have no hypoglycemic effect. An extended release preparation is available.

Glimepiride is available as 1, 2 and 4 mg tablets. It has a long duration of effect with a half-life of 5 hours allowing once or twice daily dosing. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound. A single daily dose of 1 mg/d has been shown to be effective, and the maximal recommended dose is 8 mg. It is completely metabolized by the liver to relatively inactive metabolic products.

B. Meglitinide analogs—Repaglinide is structurally similar to glyburide but lacks the sulfonic acid-urea moiety. It acts by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. It is rapidly absorbed from the intestine and then undergoes complete metabolism in the liver to inactive biliary products, giving it a plasma half-life of < 1 hour. The medication therefore causes a brief but rapid pulse of insulin. The starting dose is 0.5 mg three times a day 15 minutes before each meal. The dose can be titrated to a maximal daily dose of 16 mg.

Like the sulfonylureas, repaglinide can be used in combination with metformin. Hypoglycemia is the main side effect. In clinical trials, when the medication was compared with a long-duration sulfonylurea (glyburide), there was a trend toward less hypoglycemia. Like the sulfonylureas also, repaglinide causes weight gain. Metabolism is by cytochrome P450 3A4 isoenzyme, and other medications that induce or inhibit this isoenzyme may increase or inhibit (respectively) the metabolism of repaglinide. The medication may be useful in patients with kidney impairment or in the elderly.

Mitiglinide is a benzoylsuccinic acid derivative that binds to the sulfonylurea receptor and is similar to repaglinide in its clinical effects. It has been approved for use in Japan.

C. d-Phenylalanine derivative—Nateglinide stimulates insulin secretion by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. This compound is rapidly absorbed from the intestine, reaching peak plasma levels within 1 hour. It is metabolized in the liver and has a plasma half-life of about 1.5 hours. Like repaglinide, it causes a brief rapid pulse of insulin, and when given before a meal it reduces the postprandial rise in blood glucose. The medication is available as 60 and 120 mg tablets. The 60 mg dose is used in patients who have mild elevations in HbA1c. For most patients, the recommended starting and maintenance dose is 120 mg three times a day before meals. Like the other insulin secretagogues, its main side effects are hypoglycemia and weight gain.

2. Medications that primarily lower glucose levels by their actions on the liver, muscle, and adipose tissue—

A. Metformin—Metformin (1,1-dimethylbiguanide hydrochloride) is used, either alone or in conjunction with other oral agents or insulin, in the treatment of patients with type 2 diabetes. Metformin activates adenosine monophosphate-activated protein kinase (AMPK) by uncoupling mitochondrial oxidative phosphorylation and increasing cellular AMPK levels. Metformin’s therapeutic effects primarily derive from the
increasing hepatic AMPK activity, which reduces hepatic gluconeogenesis and lipogenesis. Metformin is a substrate for organic cation transporter 1, which is abundantly expressed in hepatocytes and in the gut.

Metformin has a half-life of 1.5–3 hours, is not bound to plasma proteins, and is not metabolized in humans, being excreted unchanged by the kidneys.

**Metformin is the first-line therapy for patients with type 2 diabetes.** The current recommendation is to start this medication at diagnosis. A side benefit of metformin therapy is its tendency to improve both fasting and postprandial hyperglycemia and hypertriglyceridemia in obese diabetics without the weight gain associated with insulin or sulfonylurea therapy. Metformin is ineffective in patients with type 1 diabetes. Patients with chronic kidney disease (calculated glomerular filtration rate < 50 mL/min) should not be given this medication because failure to excrete it would produce high blood and tissue levels of metformin that could stimulate lactic acid overproduction. Likewise, patients with liver failure or patients who abuse alcohol should not receive this medication; lactic acid production from the gut and other tissues, which rises during metformin therapy, could result in lactic acidosis when defective hepatocytes cannot remove the lactate or when alcohol-induced reduction of nucleotides interferes with lactate clearance.

**Metformin is dispensed as 500 mg, 850 mg, and 1000 mg tablets.** A 500 mg and 750 mg extended-release preparation is also available. Although the maximal dosage is 2.5 g, little benefit is seen above a total dose of 2000 mg. It is important to begin with a low dose and increase the dosage very gradually in divided doses—taken with meals—to reduce minor gastrointestinal upsets. A common schedule would be one 500 mg tablet three times a day with meals or one 850 mg or 1000 mg tablet twice daily at breakfast and dinner. Up to 2000 mg of the extended-release preparation can be given once a day.

The most frequent side effects of metformin are gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal discomfort, diarrhea), which occur in up to 20% of patients. These effects are dose-related, tend to occur at onset of therapy, and often are transient. However, in 3–5% of patients, therapy may have to be discontinued because of persistent diarrheal discomfort. In a retrospective analysis, it has been reported that patients switched from immediate-release metformin to comparable dose of extended-release metformin experienced fewer gastrointestinal side effects.

Hypoglycemia does not occur with therapeutic doses of metformin, which permits its description as a “euglycemic” or “antihyperglycemic” medication rather than an oral hypoglycemic agent. Dermatologic or hematologic toxicity is rare. Absorption of vitamin B₁₂ appears to be reduced during long-term metformin therapy, but the serum vitamin B₁₂ levels usually remain in the normal range. However, periodic screening with serum vitamin B₁₂ levels should be considered, especially in patients with symptoms of peripheral neuropathy or if a macrocytic anemia develops.

Lactic acidosis has been reported as a side effect but is uncommon with metformin in contrast to phenformin. While therapeutic doses of metformin reduce lactate uptake by the liver, serum lactate levels rise only minimally if at all, since other organs such as the kidney can remove the slight excess. However, if tissue hypoxia occurs, the metformin-treated patient is at higher risk for lactic acidosis due to compromised lactate removal. Similarly, when kidney function deteriorates, affecting not only lactate removal by the kidney but also metformin excretion, plasma levels of metformin rise far above the therapeutic range and block hepatic uptake enough to provoke lactic acidosis without associated increases in lactic acid production. Almost all reported cases have involved subjects with associated risk factors that should have contraindicated its use (kidney, liver, or cardiopulmonary insufficiency, alcoholism, advanced age). Acute kidney failure can occur rarely in certain patients receiving radiocontrast agents. Metformin therapy should therefore be temporarily halted on the day of radiocontrast administration and restarted a day or two later after confirmation that renal function has not deteriorated.

**B. Thiazolidinediones**—Medications of this class of antihyperglycemic agents sensitize peripheral tissues to insulin. They bind a nuclear receptor called peroxisome proliferator-activated receptor gamma (PPAR-γ) and affect the expression of a number of genes. Observed effects of thiazolidinediones include increased glucose transporter expression (GLUT 1 and GLUT 4), decreased free fatty acid levels, decreased hepatic glucose output, increased adiponectin and decreased release of resistin from adipocytes, and increased differentiation of preadipocytes into adipocytes. They have also been demonstrated to decrease levels of plasminogen activator inhibitor type 1, matrix metalloproteinase 9, C-reactive protein, and interleukin 6. Like the biguanides, this class of medications does not cause hypoglycemia.

Troglitazone, the first medication in this class to go into widespread clinical use, was withdrawn from clinical use because of medication-associated fatal liver failure. Two other medications of this class, rosiglitazone and pioglitazone, are available for clinical use. Both are effective as monotherapy and in combination with sulfonylureas or metformin or insulin, lowering HbA₁c by 1% to 2%. When used in combination with insulin, they can result in a 30–50% reduction in insulin dosage, and some patients can come off insulin completely. The dosage of rosiglitazone is 4–8 mg daily and of pioglitazone, 15–45 mg daily, and the medications do not have to be taken with food. Rosiglitazone is primarily metabolized by the CYP 2C8 isoenzyme and pioglitazone is metabolized by CYP 2C8 and CYP 3A4.

The combination of a thiazolidinedione and metformin has the advantage of not causing hypoglycemia. Patients inadequately managed on sulfonylureas can do well on a combination of sulfonylurea and rosiglitazone or pioglitazone. About 25% of patients in clinical trials fail to respond to these medications, presumably because they are significantly insulinopenic.

These medications have some additional effects apart from glucose lowering. Rosiglitazone therapy is associated with increases in total cholesterol, LDL-cholesterol (15%),
and HDL-cholesterol (10%). There is a reduction in free fatty acids of about 8–15%. The changes in triglycerides were generally not different from placebo. Pioglitazone in clinical trials lowered triglycerides (9%) and increased HDL-cholesterol (15%), but did not cause a consistent change in total cholesterol and LDL-cholesterol levels. A prospective randomized comparison of the metabolic effects of pioglitazone and rosiglitazone on patients who had previously taken troglitazone (now withdrawn from the US market) showed similar effects on HbA1c and weight gain. Pioglitazone-treated persons, however, had lower total cholesterol, LDL-cholesterol, and triglycerides when compared with rosiglitazone-treated persons. Small prospective studies have demonstrated that treatment with these medications leads to improvements in the biochemical and histologic features of nonalcoholic fatty liver disease. The thiazolidinediones also may limit vascular smooth muscle proliferation after injury, and there are reports that pioglitazone and troglitazone (subsequently withdrawn from the US market) reduced neointimal proliferation after coronary stent placement. Finally, in one double-blind, placebo-controlled study, rosiglitazone was shown to be associated with a decrease in the ratio of urinary albumin to creatinine excretion.

Safety concerns and some troublesome side effects have emerged about this class of medications that significantly limit their use.

A meta-analysis of 42 randomized clinical trials with rosiglitazone suggested that this medication increases the risk of angina pectoris or myocardial infarction. A meta-analysis of clinical trials with pioglitazone did not show similar findings. Although conclusive data are lacking, the European Medicines Agency has suspended the use of rosiglitazone in Europe. In the United States, the FDA has established a restricted distribution program, and prescribers and patients must enroll in the Avandia-Rosiglitazone Medicine Access Program at 1-800-282-6342 or www.avandia.com. The patients are required to review statements regarding the cardiovascular safety of rosiglitazone and acknowledge that they understand the risks. Since pioglitazone and rosiglitazone are therapeutically equivalent and side effects, apart from the myocardial infarction risk, are identical, there is no clinical reason why any patient should be prescribed rosiglitazone.

Edema occurs in about 3–4% of patients receiving monotherapy with rosiglitazone or pioglitazone. The edema occurs more frequently (10–15%) in patients receiving concomitant insulin therapy and may result in congestive heart failure. The medications are contraindicated in diabetic individuals with New York Heart Association class III and IV cardiac status. Thiazolidinediones have also been reported as being associated with new onset or worsening macular edema. Apparently, this is a rare side effect, and most of these patients also had peripheral edema. The macular edema resolved or improved once the medication was discontinued.

In experimental animals, rosiglitazone stimulates bone marrow adipogenesis at the expense of osteoblastogenesis resulting in a decrease in bone density. An increase in fracture risk in women (but not men) has been reported with both rosiglitazone and pioglitazone. The fracture risk is in the range of 1.9 per 100 patient-years with the thiazolidinedione compared to 1.1 per 100 patient years on comparison treatment. In at least one study of rosiglitazone, the fracture risk was increased in premenopausal as well as postmenopausal women.

Other side effects include anemia, which occurs in 4% of patients treated with these medications; it may be due to a dilutional effect of increased plasma volume rather than a reduction in red cell mass. Weight gain occurs, especially when the medication is combined with a sulfonylurea or insulin. Some of the weight gain is fluid retention, but there is also an increase in total fat mass. In preclinical studies with pioglitazone, bladder tumors were observed in male rats receiving clinically relevant doses of the medication. In a planned 5-year interim analysis of data from a long-term observational cohort study of patients taking pioglitazone, there was no overall increased risk of bladder cancer with pioglitazone. However, increased bladder cancer risk was observed with increasing dose and duration of pioglitazone use, reaching statistical significance after 24 months of exposure.

Although rosiglitazone and pioglitazone have not been reported to cause liver injury, the FDA recommends that they should not be used in patients with clinical evidence of active liver disease or pretreatment elevation of the alanine aminotransferase (ALT) level that is 2.5 times greater than the upper limit of normal. Obviously, caution should be used in initiation of therapy in patients with even mild ALT elevations. Liver biochemical tests should be performed prior to initiation of treatment and periodically thereafter.

3. Medications that affect absorption of glucose—α-Glucosidase inhibitors competitively inhibit the α-glucosidase enzymes in the gut that digest dietary starch and sucrose. Two of these medications—acarbose and miglitol—are available for clinical use in the United States. Voglibose, another α-glucosidase inhibitor is available in Japan, Korea, and India. Acarbose and miglitol are potent inhibitors of glucoamylase, α-amylase, and sucrase but have less effect on isomaltase and hardly any on trehalase and lactase. Acarbose binds 1000 times more avidly to the intestinal disaccharidases than do products of carbohydrate digestion or sucrose. A fundamental difference between acarbose and miglitol is in their absorption. Acarbose has the molecular mass and structural features of a tetrasaccharide, and very little (about 2%) crosses the microvillar membrane. Miglitol, however, has a structural similarity with glucose and is absorbable. Both medications delay the absorption of carbohydrate and lower postprandial glycemic excursion.

A. ACARBOSE—Acarbose is available as 50 mg and 100 mg tablets. The recommended starting dose of acarbose is 50 mg twice daily, gradually increasing to 100 mg three times daily. For maximal benefit on postprandial hyperglycemia, acarbose should be given with the first mouthful of food ingested. In diabetic patients, it reduces postprandial hyperglycemia by 30–50%, and its overall effect is to lower the HbA1c by 0.5–1%. 
The principal adverse effect, seen in 20–30% of patients, is flatulence. This is caused by undigested carbohydrate reaching the lower bowel, where gases are produced by bacterial flora. In 3% of cases, troublesome diarrhea occurs. This gastrointestinal discomfort tends to discourage excessive carbohydrate consumption and promotes improved compliance of type 2 patients with their diet prescriptions. When acarbose is given alone, there is no risk of hypoglycemia. However, if combined with insulin or sulfonylureas, it might increase the risk of hypoglycemia from these agents. A slight rise in hepatic aminotransferases has been noted in clinical trials with acarbose (5% versus 2% in placebo controls, and particularly with doses > 300 mg/d). The levels generally return to normal on stopping the medication.

In the UKPDS, approximately 2000 patients on diet, sulfonylurea, metformin, or insulin therapy were randomized to acarbose or placebo therapy. By 3 years, 60% of the patients had discontinued the medication, mostly because of gastrointestinal symptoms. If one looked only at the 40% who remained on the medication, they had an 0.5% lower HbA1c compared with placebo.

B. Miglitol—Miglitol is similar to acarbose in terms of its clinical effects. It is indicated for use in diet- or sulfonylurea-treated patients with type 2 diabetes. Therapy is initiated at the lowest effective dosage of 25 mg three times a day. The usual maintenance dose is 50 mg three times a day, although some patients may benefit from increasing the dose to 100 mg three times a day. Gastrointestinal side effects occur as with acarbose. The medication is not metabolized and is excreted unchanged by the kidney. Theoretically, absorbable α-glucosidase inhibitors could induce a deficiency of one or more of the α-glucosidases involved in cellular glycogen metabolism and biosynthesis of glycoproteins. This does not occur in practice because, unlike the intestinal mucosa, which sees a high concentration of the medication, the blood level is 200-fold to 1000-fold lower than the concentration needed to inhibit intracellular α-glucosidases. Miglitol should not be used in end-stage chronic kidney disease, when its clearance would be impaired.

4. Incretins—Oral glucose provokes a threefold to fourfold higher insulin response than an equivalent dose of glucose given intravenously. This is because the oral glucose causes a release of gut hormones, principally glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinnotropic polypeptide (GIP1), that amplify the glucose-induced insulin release. This “incretin effect” is reduced in patients with type 2 diabetes. GLP-1 secretion (but not GIP1 secretion) is impaired in patients with type 2 diabetes and when GLP-1 is infused in patients with type 2 diabetes, it stimulates insulin secretion and lowers glucose levels. GLP-1, unlike the sulfonylureas, has only a modest insulin stimulatory effect at normoglycemic concentrations. This means that GLP-1 has a lower risk for hypoglycemia than the sulfonylureas.

In addition to its insulin stimulatory effect, GLP-1 also has a number of other pancreatic and extrapancreatic effects. It suppresses glucagon secretion and so may ameliorate the hyperglucagonemia that is present in people with diabetes and improve postprandial hyperglycemia. GLP-1 preserves islet integrity and reduces apoptotic cell death of human islet cells in culture. In mice, streptozotocin-induced apoptosis is significantly reduced by coadministration of exendin-4 or exenatide, a GLP-1 receptor agonist. GLP-1 acts on the stomach delaying gastric emptying; the importance of this effect on glucose lowering is illustrated by the observation that antagonizing the deceleration of gastric emptying markedly reduces the glucose lowering effect of GLP-1. GLP-1 receptors are present in the central nervous system, and intracerebroventricular administration of GLP-1 in wild type mice, but not in GLP-1 receptor knockout mice, inhibits feeding. Type 2 diabetic patients undergoing GLP-1 infusion are less hungry; it is unclear whether this is mainly due to a deceleration of gastric emptying or whether there is a central nervous system effect as well.

A. GLP-1 RECEPTOR AGONISTS—GLP-1 is rapidly proteolyzed by dipeptidyl peptidase 4 (DPP-4) and by other enzymes, such as endopeptidase 24.11, and is also cleared rapidly by the kidney. As a result, GLP-1’s half-life is only 1–2 minutes. The native peptide, therefore, cannot be used therapeutically and the approach taken has been to develop metabolically stable analogs or derivatives of GLP-1 that are not subject to the same enzymatic degradation or renal clearance. Two GLP-1 receptor agonists, exenatide and liraglutide, are currently available for clinical use.

Exenatide (Exendin 4) is a GLP-1 receptor agonist isolated from the saliva of the Gila Monster (a venemous lizard) that is more resistant to DPP-4 action and cleared by the kidney. Its half-life is 2.4 hours, and its glucose lowering effect is about 6 hours. When this medication is given to patients with type 2 diabetes by subcutaneous injection twice daily, it lowers blood glucose and HbA1c levels. Exenatide appears to have the same effects as GLP-1 on glucagon suppression and gastric emptying. In clinical trials, adding exenatide therapy to patients with type 2 diabetes already taking metformin or a sulfonylurea, or both, further lowered the HbA1c value by 0.4% to 0.6% over a 30-week period. These patients also experienced a weight loss of 3–6 pounds. In an open label extension study up to 80 weeks, the HbA1c reduction was sustained, and there was further weight loss (to a total loss of about 10 pounds). The main side effect was nausea, affecting over 40% of the patients. The nausea was dose-dependent and declined with time. The risk of hypoglycemia was higher in persons taking sulfonylureas. The FDA has received 30 post-marketing reports of acute pancreatitis in patients taking exenatide. The pancreatitis was severe (hemorrhagic or necrotizing) in 6 instances, and two of these patients died. Many of these patients had other risk factors for pancreatitis, but the possibility remains that the medication was causally responsible for some cases. Patients taking exenatide should be advised to seek immediate medical care if they experience unexplained persistent severe abdominal pain. The FDA also reported 16 cases of renal impairment and 62 cases of acute renal failure in patients taking exenatide. Some of these patients had preexisting kidney disease, and others had one or more risk factors for kidney disease. A number of patients reported nausea,
vomiting, and diarrhea; it is possible that these side effects cause volume depletion and contributed to the development of the renal failure. The delay in gastric emptying may affect the absorption of some other medications; therefore, antibiotics and oral contraceptives should be taken 1 hour before exenatide doses. Low-titer antibodies against exenatide develop in over one-third (38%) of patients, but the clinical effects are not attenuated. High-titer antibodies develop in a subset of patients (~6%), and in about half of these cases, an attenuation of glycemic response has been seen. Exenatide stimulates C-cell tumors in rodents and the drug is therefore contraindicated in patients with a personal or family history of medullary thyroid cancer or multiple endocrine neoplasia (MEN) syndrome type 2.

Exenatide is dispensed as two fixed-dose pens (5 mcg and 10 mcg). It is injected 60 minutes before breakfast and before dinner. Patients should be prescribed the 5 mcg pen for the first month and, if tolerated, the dose can then be increased to 10 mcg twice a day. The medication is not recommended in patients with glomerular filtration rate < 30 mL/min.

Exenatide LAR is a once weekly preparation that is dispensed as a powder (2 mg). It is suspended in the provided diluent just prior to injection. In comparative clinical trials, the long-acting drug lowers the HbA\textsubscript{1c} level a little more than the twice daily drug. It is as well tolerated, with nausea being the predominant side effect.

Liraglutide is a soluble fatty acid acylated GLP-1 analog (with replacement of lysine with arginine at position 34 and the attachment of a C16 acyl chain to a lysine at position 26). The fatty-acyl GLP-1 retains affinity for GLP-1 receptors but the addition of the C16 acyl chain allows for non-covalent binding to albumin, both hindering DPP-4 access to the molecule and contributing to a prolonged half-life and duration of action. The half-life is approximately 12 hours, allowing the medication to be injected once a day.

In clinical trials lasting 26 and 52 weeks, adding liraglutide to the therapeutic regimen (metformin, sulfonylurea, thiazolidinedione) of patients with type 2 diabetes further lowered the HbA\textsubscript{1c} value. Depending on the dose and design of the study, the HbA\textsubscript{1c} decline was in the range of 0.6% to 1.5%. The patients had sustained weight loss of 1–6 pounds.

Like exenatide, the most frequent side effects were nausea (28%) and vomiting (10%). There was also an increased incidence of diarrhea. About 2–5% of participants withdrew from the studies because of the gastrointestinal symptoms. In clinical trials, there were seven cases of pancreatitis in the liraglutide treated group with one case in the comparison group (2.2 vs. 0.6 cases per 1000 patient-years). Liraglutide stimulates C-cell neoplasia and causes medullary thyroid carcinoma in rats. Human C-cells express very few GLP-1 receptors, and the relevance to human therapy is unclear; however, because of the animal data, the medication should not be used in patients with personal or family history of medullary thyroid carcinoma or multiple endocrine neoplasia (MEN) syndrome type 2.

The dosing is initiated at 0.6 mg daily, increased after 1 week to 1.2 mg daily. If needed, an additional increase in dose to 1.8 mg is recommended for optimal glycemic control. Titration is also based on tolerability. There is limited experience using the medication in renal failure but no dose adjustment is recommended.

**B. DPP-4 inhibitors**—An alternate approach to the use of GLP-1 receptor agonists is to inhibit the enzyme DPP-4 and prolong the action of endogenously released GLP-1 and GIP. Three oral DPP-4 inhibitors, sitagliptin, saxagliptin, and linagliptin, are available for the treatment of type 2 diabetes in the United States. An additional DPP4 inhibitor, vildagliptin, is available in Europe.

**Sitagliptin** in clinical trials was shown to be effective in lowering glucose when used alone and in combination with metformin and pioglitazone. In various clinical trials, improvements in HbA\textsubscript{1c} ranged from 0.5% to 1.4%. The usual dose of sitagliptin is 100 mg once daily, but the dose is reduced to 50 mg daily if the calculated creatinine clearance is 30–50 mL/min and to 25 mg for clearances < 30 mL/min. Unlike exenatide, sitagliptin does not cause nausea or vomiting. It also does not result in weight loss. The main adverse effect appears to be a predisposition to nosopharyngitis or upper respiratory tract infection. A small increase in neutrophil count of ~200 cells/μL has also occurred. Since its FDA approval and clinical use, there have been reports of serious allergic reactions to sitagliptin, including anaphylaxis, angioedema, and exfoliative skin conditions including Stevens-Johnson syndrome. There have also been reports of pancreatitis (88 cases including 2 cases of hemorrhagic or necrotizing pancreatitis). The frequency of these events is unclear. A number of neuropeptides, growth factors, cytokines, and chemokines are potential DPP-4 substrates; DPP-4 inhibitors prolong the actions of neuropeptide Y and substance P. It is unknown whether the effects of DPP-4 inhibitors on the actions of neuropeptide Y and substance P over a long-term period will have negative consequences.

**Saxagliptin**, when added to the therapeutic regimen (metformin, sulfonylurea, thiazolidinedione) of patients with type 2 diabetes, further lowered the HbA\textsubscript{1c} value by about 0.7–0.9%. The dose is 2.5 mg or 5 mg once a day. The 2.5-mg dose should be used in patients with calculated creatinine clearance < 50 mL/min. It lowers HbA\textsubscript{1c} by about 0.6% when added to metformin or glyburide or thiazolidine in various 24-week clinical trials. The medication does not cause weight gain or loss. The main adverse reactions were upper respiratory tract infection, nasopharyngitis, headache, and edema, occurred in 1.5% of patients taking the medication compared with 0.4% receiving placebo. The metabolism of saxagliptin is by CYP3A4/5; thus, strong inhibitors or inducers of CYP3A4/5 will affect the pharmacokinetics of saxagliptin and its active metabolite.

**Linagliptin** lowers HbA\textsubscript{1c} by about 0.4–0.6% when added to metformin, sulfonylurea, or pioglitazone. The dose is 5 mg daily and, since it is primarily excreted unmetabolized via the bile, no dose adjustment is needed in patients with renal failure.
patients with renal failure. The adverse reactions include nasopharyngitis and hypersensitivity reactions (urticaria, angioedema, localized skin exfoliation, bronchial hyperreactivity). In one study, there were eight cases of pancreatitis in 4687 patients exposed to drug (4311 patient years) with 0 cases in 1183 patients receiving placebo (433 patient years).

Vildagliptin lowers HbA1c by about 0.5–1% when added to the therapeutic regimen of patients with type 2 diabetes. The dose in 50 mg once or twice daily. Adverse reactions include upper respiratory tract infections, nasopharyngitis, dizziness, and headache. Rare cases of hepatic dysfunction, including hepatitis, have been reported. Liver function testing is recommended quarterly during the first year of use and periodically thereafter.

5. Others—Pramlintide is a synthetic analog of islet amyloid polypeptide (IAPP or amylin). When given subcutaneously, it delays gastric emptying, suppresses glucagon secretion, and decreases appetite. It is approved for use both in type 1 diabetes and in insulin-treated type 2 diabetes. In 6-month clinical studies with type 1 and insulin-treated type 2 patients, those taking the medication had an approximately 0.4% reduction in HbA1c, and about 1.7 kg weight loss compared with placebo. The HbA1c reduction was sustained for 2 years but some of the weight was regained. The medication is given by injection immediately before the meal. Hypoglycemia can occur, and it is recommended that the short-acting or premixed insulin doses be reduced by 50% when the medication is started. Since the medication slows gastric emptying, recovery from hypoglycemia can be a problem because of delay in absorption of fast-acting carbohydrates. Nausea was the other main side effect, affecting 30–50% of persons but tended to improve with time. In patients with type 1 diabetes, the initial dose of pramlintide is 15 mcg before each meal and titrated up by 15 mcg increments to a maintenance dose of 30 mcg or 60 mcg before each meal. In patients with type 2 diabetes, the starting dose is 60 mcg premeals increased to 120 mcg in 3 to 7 days if no significant nausea occurs.

6. Medication combinations—Several medication combinations are available in different dose sizes, including glyburide and metformin (Glucovance); glipizide and metformin (Metaglip); repaglinide and metformin (Prandi-Met); rosiglitazone and metformin (Avandamet); pioglitazone and metformin (ACTOplus Met); rosiglitazone and gliclazide (Avandaryl); pioglitazone and glimepiride (Duetact); sitagliptin and metformin (Janumet); saxagliptin and metformin XR (Kombiglyze XR); and linagliptin and metformin (Jentadueto). These medication combinations, however, limit the clinician’s ability to optimally adjust dosage of the individual medications and for that reason are not recommended.

C. Insulin

Insulin is indicated for type 1 diabetes as well as for type 2 diabetic patients with insulinopenia whose hyperglycemia does not respond to diet therapy either alone or combined with other hypoglycemic medications.

With the development of highly purified human insulin preparations, immunogenicity has been markedly reduced, thereby decreasing the incidence of therapeutic complications such as insulin allergy, immune insulin resistance, and localized lipatrophy at the injection site. However, the problem of achieving optimal insulin delivery remains unsolved with the present state of technology. It has not been possible to reproduce the physiologic patterns of intraportal insulin secretion with subcutaneous injections of short-acting or longer-acting insulin preparations. Even so, with the help of appropriate modifications of diet and exercise and careful monitoring of capillary blood glucose levels at home, it has often been possible to achieve acceptable control of blood glucose by using various mixtures of short- and longer-acting insulins injected at least twice daily or portable insulin infusion pumps.

1. Characteristics of available insulin preparations—Commercial insulin preparations differ with respect to the time of onset and duration of their biologic action (Table 27–8).

A. Species of insulin—Human insulin is produced by recombinant DNA techniques (biosynthetic human insulin) as Humulin (Eli Lilly) and as Novolin (Novo Nordisk). It is dispensed as either regular (R) or NPH (N) formulations. Five analogs of human insulin—three rapidly acting (insulin lispro, insulin aspart, insulin glulisine) and two long-acting (insulin glargine and insulin detemir)—have been approved by the FDA for clinical use (Table 27–9). Animal insulins are no longer available in the United States.

B. Purity of insulin—“Purified” insulin is defined by FDA regulations as the degree of purity wherein proinsulin contamination is < 10 ppm. All insulins presently available contain < 10 ppm of proinsulin and are labeled as “purified.” These purified insulins seem to preserve their potency quite well, so that refrigeration is recommended but not crucial. During travel, reserve supplies of insulin can thus be readily transported for weeks without losing potency if protected from extremes of heat or cold.

C. Concentration of insulin—At present, insulins in the United States are available in a concentration of 100 units/mL (U100), and all are dispensed in 10-mL vials. With the
The popularity of "low-dose" (0.5- or 0.3-mL) disposable insulin syringes, U100 can be measured with acceptable accuracy in doses as low as 1–2 units. For use in rare cases of severe insulin resistance in which large quantities of insulin are required, U500 regular human insulin (Humulin R) is available from Eli Lilly.

2. Insulin preparations—Insulins are classified into short-acting and long-acting insulin preparations. The short-acting preparations are regular insulin and the rapidly acting insulin analogs (Figure 27–3). They are dispensed as clear solutions at neutral pH and contain small amounts of zinc to improve their stability and shelf life. The long-acting preparations are NPH insulin and the long-acting insulin analogs. NPH insulin is dispensed as a turbid suspension at neutral pH with protamine in phosphate buffer. The long-acting insulin analogs are also dispensed as clear solutions; insulin glargine is at acidic pH and insulin detemir is at neutral pH. The rapidly acting insulin analogs and the long-acting insulins are designed for subcutaneous administration, while regular insulin can also be given intravenously. While insulin aspart has been approved for intravenous use (eg, in hyperglycemic emergencies), there is no advantage in using insulin aspart over regular insulin by this route.

¹All insulins available in the United States are recombinant human or human insulin analog origin. All the above insulins are dispensed at U100 concentration. There is an additional U500 preparation of regular insulin. NPH, neutral protamine Hagedorn.

Figure 27–3. Extent and duration of action of various types of insulin–euglycemic hyperinsulinemic clamps in normal volunteers. A. Intermediate neutral protamine Hagedorn (NPH) insulin and long-acting insulin analogs. B. Regular insulin and rapidly acting insulin analogs.
A. Short-acting insulin preparations—

1. Regular insulin—Regular insulin is a short-acting soluble crystalline zinc insulin whose effect appears within 30 minutes after subcutaneous injection and lasts 5–7 hours when usual quantities are administered. Intravenous infusions of regular insulin are particularly useful in the treatment of diabetic ketoacidosis and during the perioperative management of insulin-requiring diabetics. Regular insulin is indicated when the subcutaneous insulin requirement is changing rapidly, such as after surgery or during acute infections—although the rapidly acting insulin analogs may be preferable in these situations.

For markedly insulin-resistant persons who would otherwise require large volumes of insulin solution, a U500 preparation of human regular insulin is available. Since a U500 syringe is not available, when U500 insulin is required in cases of severe insulin resistance, a U100 insulin syringe or tuberculin syringe must be used to measure doses. The clinician should carefully note dosages in both units and volume to avoid overdosage.

2. Rapidly acting insulin analogs—Insulin lispro (Humalog) is an insulin analog produced by recombinant technology, wherein two amino acids near the carboxyl terminal of the B chain have been reversed in position: Proline at position B28 has been moved to B29 and lysine has been moved from B29 to B28. Insulin aspart (Novolog) is a single substitution of proline by aspartic acid at position B28. Insulin glulisine (Apidra) differs from human insulin in that the amino acid asparagine at position B3 is replaced by lysine and the lysine in position B29 by glutamic acid. These changes result in these three analogs having less tendency to form hexamers, in contrast to human insulin. When injected subcutaneously, the analogs quickly dissociate into monomers and are absorbed very rapidly, reaching peak serum values in as soon as 1 hour—in contrast to regular human insulin, whose hexamers require considerably more time to dissociate and become absorbed. The amino acid changes in these analogs do not interfere with their binding to the insulin receptor, with the circulating half-life, or with their immunogenicity, which are all identical with those of human regular insulin.

Clinical trials have demonstrated that the optimal times of preprandial subcutaneous injection of comparable doses of the rapidly acting insulin analogs and of regular human insulin are 20 minutes and 60 minutes, respectively, before the meal. While this more rapid onset of action has been welcomed as a great convenience by diabetic patients who object to waiting as long as 60 minutes after injecting regular human insulin before they can begin their meal, patients must be taught to ingest adequate absorbable carbohydrate early in the meal to avoid hypoglycemia during the meal. Another desirable feature of rapidly acting insulin analogs is that their duration of action remains at about 4 hours irrespective of dosage. This contrasts with regular insulin, whose duration of action is prolonged when larger doses are used.

The rapidly acting analogs are also commonly used in pumps. In a double-blind crossover study comparing insulin lispro with regular insulin in insulin pumps, persons using insulin lispro had lower HbA1c values and improved postprandial glucose control with the same frequency of hypoglycemia. The concern remains that in the event of pump failure, users of the rapidly acting insulin analogs will have more rapid onset of hyperglycemia and ketosis.

B. Long-acting insulin preparations—

1. NPH (neutral protamine Hagedorn or isophane) insulin—NPH is an intermediate-acting insulin whose onset of action is delayed by combining 2 parts soluble crystalline zinc insulin with 1 part protamine zinc insulin. This produces equivalent amounts of insulin and protamine, so that neither is present in an uncomplexed form (“isophane”).

Its onset of action is delayed to 2–4 hours, and its peak response is generally reached in about 8–10 hours. Because its duration of action is often < 24 hours (with a range of 10–20 hours), most patients require at least two injections daily to maintain a sustained insulin effect. Occasional vials of NPH insulin have tended to show unusual clumping of their contents or “frosting” of the container, with considerable loss of bioactivity. This instability is rare and occurs less frequently if NPH human insulin is refrigerated when not in use and if bottles are discarded after 1 month of use.

2. Insulin glargine—Insulin glargine is an insulin analog in which the asparagine at position 21 of the A chain of the human insulin molecule is replaced by glycine and two arginines are added to the carboxyl terminal of the B chain. The arginines raise the isoelectric point of the molecule closer to neutral, making it more soluble in an acidic environment. In contrast, human insulin has an isoelectric point of pH 5.4. Insulin glargine is a clear insulin which, when injected into the neutral pH environment of the subcutaneous tissue, forms microprecipitates that slowly release the insulin into the circulation. It lasts for about 24 hours without any pronounced peaks and is given once a day to provide basal coverage. This insulin cannot be mixed with the other human insulins because of its acidic pH. When this insulin was given as a single injection at bedtime to type 1 patients, fasting hyperglycemia was better controlled when compared with bedtime NPH insulin. The clinical trials also suggest that there may be less nocturnal hypoglycemia with this insulin when compared with NPH insulin.

In one clinical trial involving type 2 patients, insulin glargine was associated with a slightly higher progression of retinopathy when compared with NPH insulin. The frequency was 7.3% with the analog and 2.7% with the NPH. However, this observation was not confirmed in a 5-year open-label prospective study of 1024 persons randomized to NPH or insulin glargine. Insulin glargine does have a sixfold greater affinity for IGF-1 receptor compared with the human insulin. There has also been a report that insulin glargine had increased mitogenicity compared with human insulin in a human osteosarcoma cell line. The significance of these observations is not yet clear. An observational study from Germany of 127,031 patients who had exposure to regular insulin, short-acting insulin analogs, and insulin glargine reported a strong correlation between increased insulin dose and cancer risk. Moreover, insulin glargine, dose for dose, appeared to carry a higher risk of
cancer than regular insulin. Additional studies are needed
to confirm or refute this observation. Because of lack of
safety data, use of insulin glargine during pregnancy is not
recommended.

(3) Insulin detemir—Insulin detemir is an insulin ana-
log in which the tyrosine at position 30 of the B chain has
been removed and a 14-C fatty acid chain (tetradecanoic
acid) is attached to the lysine at position 29 by acylation.
The fatty acid chain makes the molecule more lipophilic
than native insulin and the addition of zinc stabilizes
the molecule and leads to formation of hexamers. After injec-
tion, self-association at the injection site and albumin
binding in the circulation via the fatty acid side chain, leads
to slower distribution to peripheral target tissues and pro-
longed duration of action. The affinity of insulin detemir is
fourfold to fivefold lower than that of human soluble insu-
lin and therefore the U100 formulation of insulin detemir
has an insulin concentration of 2400 nmol/mL compared
with 600 nmol/mL for NPH. The duration of action for
insulin detemir is about 17 hours at therapeutically rele-
vant doses. It is recommended that the insulin be injected
once or twice a day to achieve a stable basal coverage. This
insulin has been reported to have lower within-subject
pharmacodynamic variability compared with NPH insulin
and insulin glargine. In vitro studies do not suggest any
clinically relevant albumin binding interactions between
insulin detemir and fatty acids or protein-bound medi-
cations. Since there is a vast excess (~400,000) of albumin
binding sites available in plasma per insulin detemir mol-
ecule, it is unlikely that hypoalbuminemic disease states
will affect the ratio of bound to free insulin detemir.

C. Mixed insulin preparations—Since intermediate
insulins require several hours to reach adequate therapeu-
tic levels, their use in patients with type 1 diabetes requires
supplements of regular or rapidly acting insulin analogs
preprandially. For convenience, regular or rapidly acting
insulin analogs and NPH insulin may be mixed together in
the same syringe and injected subcutaneously in split dos-
age before breakfast and supper. It is recommended that
the regular insulin or rapidly acting insulin analog be with-
drawn first, then the NPH insulin and that the injection be
given immediately after loading the syringe. Stable pre-
mixed insulins (70% NPH and 30% regular) are available
as a convenience to patients who have difficulty mixing
insulin because of visual problems or impairment of
manual dexterity. Premixed preparations of insulin lispro
and NPH insulins are unstable because of exchange of
insulin lispro with the human insulin in the protamine
complex. Consequently, the soluble component becomes
over time a mixture of regular and insulin lispro at varying
ratios. In an attempt to remedy this, an intermediate insu-
lin composed of isophane complexes of protamine with
insulin lispro was developed called NPL (neutral protamine
lispro). This insulin has the same duration of action as
NPH insulin. Premixed combinations of NPL and insulin
lispro—(75% NPL/25% insulin lispro mixture [Humalog
Mix 75/25]) and 50% NPL/50% insulin lispro mixture
[Humalog Mix 50/50]) are available for clinical use. Similarly,
a 70% insulin aspart protamine/30% insulin aspart
(NovoLog Mix 70/30) is available. The main advantages of
these mixtures are that they can be given within 15 minutes
of starting a meal and they are superior in controlling the
postprandial glucose rise after a carbohydrate rich meal.
These benefits have not translated into improvements in
HbA1c levels when compared with the usual 70% NPH/30%
regular mixture.

The longer-acting insulin analogs cannot be mixed with
either regular insulin or the rapidly acting insulin analogs.

3. Methods of insulin administration

A. Insulin syringes and needles—Plastic disposable
syringes are available in 1 mL, 0.5 mL, and 0.3 mL sizes.
The “low-dose” 0.3 mL syringes have become increasingly
popular, because many diabetics do not take more than
30 units of insulin in a single injection except in rare
instances of extreme insulin resistance. Two lengths of
needles are available: short (8 mm) and long (12.7 mm).
Long needles are preferable in obese patients to reduce
variability of insulin absorption. Ultrafine needles as small
as 31 gauge reduce the pain of injections. “Disposable”
syringes may be reused until blunting of the needle occurs
(usually after three to five injections). Sterility adequate
to avoid infection with reuse appears to be maintained by
recapping syringes between uses. Cleansing the needle with
alcohol may not be desirable since it can dissolve the silicone
coating and can increase the pain of skin puncturing.

Any part of the body covered by loose skin can be used,
such as the abdomen, thighs, upper arms, flanks, and upper
buttocks. Preparation with alcohol is no longer required
prior to injection as long as the skin is clean. Rotation of sites
continues to be recommended to avoid delayed absorption
when fibrosis or lipohypertrophy occurs from repeated use
of a single site. However, considerable variability of absorp-
tion rates from different sites, particularly with exercise, may
contribute to the instability of glycemic control in certain
type 1 patients if injection sites are rotated too frequently in
different areas of the body. Consequently, it is best to limit
injection sites to a single region of the body and rotate sites
within that region. The abdomen is recommended for sub-
cutaneous injections, since regular insulin has been shown to
absorb more rapidly from there than from other subcutaneous
sites. The effect of anatomic regions appears to be much less
pronounced with the analog insulins.

B. Insulin pen injector devices—Insulin pens elimi-
nate the need for carrying insulin vials and syringes.
Cartridges of insulin lispro, insulin aspart, and insulin
glarginyl are available for reusable pens (Eli Lilly, Novo
Nordisk, Owen Mumford, and Sanofi Aventis pens).
Disposable prefilled pens are also available for insulin lis-
pro, insulin aspart, insulin glulisine, insulin detemir, insu-
lin glargine, NPH, 70% NPH/30% regular, 75% NPL/25%
insulin lispro, 50% NPL/50% insulin lispro, and 70% insu-
lin aspart protamine/30% insulin aspart. Thirty-one gauge
needles (5, 6, and 8 mm long) for these pens make injec-
tions almost painless.

C. Insulin pumps—In the United States, Medtronic Mini-
Med, Animas, Insulet, and Roche make insulin infusion
pumps for subcutaneous delivery of insulin. These pumps
are small (about the size of a pager) and very easy to
program. They offer many features, including the ability to set a number of different basal rates throughout the 24 hours and to adjust the time over which bolus doses are given. They also are able to detect pressure build-up if the catheter is kinked. Improvements have also been made in the infusion sets. The catheter connecting the insulin reservoir to the subcutaneous cannula can be disconnected, allowing the patient to remove the pump temporarily (eg, for bathing). Ominpod (Insulet Corporation) is an insulin infusion system in which the insulin reservoir and infusion set are integrated into one unit (pod), so there is no catheter. The pod, placed on the skin, delivers subcutaneous basal and bolus insulin based on wirelessly transmitted instructions from a personal digital assistant. The great advantage of continuous subcutaneous insulin infusion (CSII) is that it allows for establishment of a basal profile tailored to the patient. The patient therefore is able to eat with less regard to timing because the basal insulin infusion should maintain constant blood glucose between meals. Also the ability to adjust the basal insulin infusion makes it easier for the patient to manage glycemic excursions that occur with exercise. The pumps also have software that can assist the patient to calculate boluses based on glucose reading and carbohydrates to be consumed. They keep track of the time elapsed since last insulin bolus and the patient is reminded of this when he or she attempts to give additional correction bolus before the effect of the previous bolus has worn off ("insulin on board" feature). This feature reduces the risk of overcorrecting and subsequent hypoglycemia.

CSII therapy is appropriate for patients with type 1 diabetes who are motivated, mechanically inclined, educated about diabetes (diet, insulin action, treatment of hypoglycemia and hyperglycemia), and willing to monitor their blood glucose four to six times a day. Known complications of CSII include ketoacidosis, which can occur when the effect of the previous bolus has worn off ("insulin on board" feature). This feature reduces the risk of overcorrecting and subsequent hypoglycemia.

D. Inhaled insulin—Exubera, the first inhaled insulin preparation approved by the FDA is no longer available; the manufacturer stopped marketing it because of lack of demand. In clinical trials, Exubera was as effective as subcutaneous regular insulin in controlling postprandial glucose excursions. Physicians, however, were reluctant to prescribe Exubera for a number of reasons, including a lack of long-term safety data on pulmonary function, awkward dosing schedule, availability of other insulin delivery systems, cost, and lack of insurance coverage. The manufacturer also subsequently reported that there were six cases of lung cancer in patients who used inhaled insulin and one case in the comparison treatment patients. All the patients in whom lung cancer developed had a history of cigarette smoking. There is currently only one pharmaceutical company conducting clinical trials with inhaled insulin (Technosphere insulin, MannKind Corporation).

D. Transplantation

Pancreas transplantation at the time of kidney transplantation is becoming more widely accepted. Patients undergoing simultaneous pancreas and kidney transplantation have an 85% chance of pancreatic graft survival and a 92% chance of kidney graft survival after 1 year. Solitary pancreatic transplantation in the absence of a need for kidney transplantation should be considered only in those rare patients who fail all other insulin therapeutic approaches and who have frequent severe hypoglycemia or who have life-threatening complications related to their lack of metabolic control.

Islet cell transplantation is a minimally invasive procedure, and investigators in Edmonton, Canada, have reported initial insulin independence in a small number of patients with type 1 diabetes who underwent this procedure. Using islets from multiple donors and corticosteroid-free immunosuppression, percutaneous transhepatic portal vein transplantation of islets was achieved in over 20 subjects. Although all of the initial cohort was able to achieve insulin independence posttransplantation (some for more than 2 years of follow-up), a decline in insulin secretion has occurred over time and the subjects have again required supplemental insulin. All patients had complete correction of severe hypoglycemic reactions, leading to a marked improvement in overall quality of life. Islet cell transplant trials with different kinds and combinations of immunosuppressive agents are currently underway. Even if long-term insulin independence is demonstrated, wide application of this procedure for the treatment of type 1 diabetes is limited by the dependence on multiple donors and the requirement for potent long-term immunotherapy.

**Steps in the Management of the Diabetic Patient**

**A. Diagnostic Examination**

Any features of the clinical picture that suggest end-organ insensitivity to insulin, such as visceral obesity, must be identified. The family history should document not only the incidence of diabetes in other members of the family...
but also the age at onset, whether it was associated with obesity, and whether insulin was required. An attempt should be made to characterize the diabetes as type 1 or type 2, based on the clinical features present and on whether or not ketonuria accompanies the glycosuria. For the occasional patient, measurement of ICA, GAD65, IAA, and ICA 512 antibodies can help distinguish between type 1 and type 2 diabetes. Many patients with newly diagnosed type 1 diabetes still have significant endogenous insulin production, and C peptide levels do not reliably distinguish between type 1 and type 2 diabetes. Other factors that increase cardiac risk, such as smoking history, presence of hypertension or hyperlipidemia, or oral contraceptive pill use, should be recorded.

Laboratory diagnosis should document fasting plasma glucose levels above 126 mg/dL (7 mmol/L) or postprandial values consistently above 200 mg/dL (11.1 mmol/L) and whether ketonuria accompanies the glycosuria. A glycohemoglobin measurement is useful for assessing the effectiveness of future therapy. Some flexibility of clinical judgment is appropriate when diagnosing diabetes mellitus in the elderly patient with borderline hyperglycemia. Baseline values include fasting plasma triglycerides, total cholesterol and HDL-cholesterol, electrocardiography, kidney function studies, peripheral pulses, and neurologic, pediatric, and ophthalmologic examinations to help guide future assessments.

B. Patient Education (Self-Management Training)

Since diabetes is a lifelong disorder, education of the patient and the family is probably the most important obligation of the clinician who provides initial care. The best persons to manage a disease that is affected so markedly by daily fluctuations in environmental stress, exercise, diet, and infections are the patients themselves and their families. The “teaching curriculum” should include explanations by the physician or nurse of the nature of diabetes and its potential acute and chronic hazards and how they can be recognized early and prevented or treated. Self-monitoring of blood glucose should be emphasized, especially in insulin-requiring diabetic patients, and instructions must be given on proper testing and recording of data.

Patients taking insulin should have an understanding of the actions of basal and bolus insulins. They should be taught to determine whether the basal dose is appropriate and how to adjust the rapidly acting insulin dose for the carbohydrate content of a meal. Patients and their families and friends should be taught to recognize signs and symptoms of hypoglycemia and how to treat low glucose reactions. Strenuous exercise can precipitate hypoglycemia, and patients must therefore be taught to reduce their insulin dosage in anticipation of strenuous activity or to take supplemental carbohydrate. Injection of insulin into a site farthest away from the muscles most involved in the exercise may help ameliorate exercise-induced hypoglycemia, since insulin injected in the proximity of exercising muscle may be more rapidly mobilized. Exercise training also increases the effectiveness of insulin and insulin doses should be adjusted accordingly. Infections can cause insulin resistance, and patients should be instructed on how to manage the hyperglycemia with supplemental rapidly acting insulin.

The targets for blood glucose control should be elevated appropriately in elderly patients since they have the greatest risk if subjected to hypoglycemia and the least long-term benefit from more rigid glycemic control. Advice on personal hygiene, including detailed instructions on foot and dental care, should be provided. All infections (especially pyogenic ones) provoke the release of high levels of insulin antagonists, such as catecholamines or glucagon, and thus bring about a marked increase in insulin requirements. Patients who are taking oral agents may decompensate and temporarily require insulin. Patients should be told about community agencies, such as Diabetes Association chapters, that can serve as a continuing source of instruction.

Finally, vigorous efforts should be made to persuade new diabetics who smoke to give up the habit, since large vessel peripheral vascular disease and debilitating retinopathy are less common in nonsmoking diabetic patients.

C. Therapy

Treatment must be individualized on the basis of the type of diabetes and specific needs of each patient. However, certain general principles of management can be outlined for hyperglycemic states of different types.

1. Type 1 diabetes—Traditional once- or twice-daily insulin regimens are usually ineffective in type 1 patients without residual endogenous insulin. In these patients, information and counseling based on the findings of the DCCT (see above) should be provided about the advantages of taking multiple injections of insulin in conjunction with self-blood glucose monitoring. If near-normalization of blood glucose is attempted, at least four measurements of capillary blood glucose and three or four insulin injections are necessary.

A combination of rapidly acting insulin analogs and long-acting insulin analogs allows for more physiologic insulin replacement. The rapidly acting insulin analogs have been advocated as a safer and much more convenient alternative to regular human insulin for prandial use. In a study comparing regular insulin with insulin lispro, daily insulin doses and HbA1c levels were similar, but insulin lispro improved postprandial control, reduced hypoglycemic episodes, and improved patient convenience compared with regular insulin. However, because of their relatively short duration (no more than 3–4 hours), the rapidly acting insulin analogs need to be combined with longer-acting insulins to provide basal coverage and avoid hyperglycemia prior to the next meal. In addition to carbohydrate content of the meal, the effect of simultaneous fat ingestion must also be considered a factor in determining the rapidly acting insulin analog dosage required to control the glycemic increment during and just after the meal. With low-carbohydrate content and high-fat intake, there is an increased risk of hypoglycemia from insulin lispro within 2 hours after the meal. Table 27–10 illustrates a regimen with a rapidly acting insulin analog and insulin detemir or insulin glargine.
Table 27–11. Examples of intensive insulin regimens using rapidly acting insulin analogs (insulin lispro, aspart, or glulisine) and insulin detemir, or insulin glargine in a 70-kg man with type 1 diabetes.1–3

effective. A bedtime dose either of insulin glargine or insu-
lin detemir provides more sustained overnight insulin levels
than human NPH and may be effective in managing
refractory prebreakfast hyperglycemia. If this fails, insulin
pump therapy may be required. When the dawn phenom-
emon alone is present, the dosage of intermediate insulin
can be divided between dinnertime and bedtime; when
insulin pumps are used, the basal infusion rate can be
increased (eg, from 0.8 unit/h to 0.9 unit/h from 6 AM
until breakfast).

2. Type 2 diabetes—Therapeutic recommendations are
based on the relative contributions of beta cell insuffi-
ciency and insulin insensitivity in individual patients. The
possibility that the individual patient has a specific etio-
logic cause for their diabetes should always be considered,
especially when the patient does not have a family history
of type 2 diabetes or does not have any evidence of central
obesity or insulin resistance. Such patients should be evalu-
ated for other types of diabetes such as LADA or MODY.
Patients with LADA should be prescribed insulin when the
disease is diagnosed and treated like patients with type 1
diabetes. It is also important to note that many patients
with type 2 diabetes mellitus have a progressive loss of beta
cell function and will require additional therapeutic inter-
ventions with time.

A. Weight reduction—One of the primary modes of
therapy in the obese patient with type 2 diabetes is weight
reduction. Normalization of glycemia can be achieved by
weight loss and improvement in tissue sensitivity to insu-
lin. A combination of caloric restriction, increased exercise,
and behavior modification is required if a weight reduction
program is to be successful. Understanding the risks associ-
ated with the diagnosis of diabetes may motivate the
patient to lose weight.

For selected patients, medical or surgical options for
weight loss should be considered (see Chapter 29).
Sibutramine, a combined serotonin-norepinephrine reuptake
inhibitor, was moderately effective in promoting weight
loss, but it was withdrawn from the US market because of
its association with increased cardiovascular risk. Orlistat is
a reversible inhibitor of gastric and pancreatic lipases and
prevents the hydrolysis and absorption of dietary trigly-
cerides. It is available over-the-counter and in prescription
strength. In 1-year studies in obese patients with type 2
diabetes, those taking orlistat had lost more weight, had
lower HbA1c values, and had improved lipid profiles. The
main adverse reactions were gastrointestinal, with oily
spotting, oily stool, flatus, and fecal urgency and frequency.
Malabsorption of fat-soluble vitamins also occurs, and
patients should take a multivitamin tablet containing fat-
soluble vitamins at least 2 hours before or 2 hours after the
administration of orlistat. Cases of severe liver injury have
been reported with this medication, although a cause and
effect relationship has not been established.

Bariatric surgery (Roux-en-Y, gastric banding, gastric
sleeve, biliopancreatic diversion/duodenal switch) typically
results in substantial weight loss and improvement in glu-
cose levels. A meta-analysis examining the impact of bariat-
ric surgery on patients with diabetes and BMI of 40 kg/m²
or greater noted that 82% of patients had resolution of
clinical and laboratory manifestations of diabetes in the
first 2 years after surgery and 62% remained free of diabetes
more than 2 years after surgery. The improvement was most
marked in the procedure that caused the greatest weight
loss (biliopancreatic diversion/duodenal switch). There
was, however, a high attrition of patients available for
follow-up, and there was little information about different
ethnic types. Weight regain does occur after bariatric sur-
gery, and it can be expected that 20–25% of the lost weight
will be regained over 10 years. The impact of this weight gain
on diabetes recurrence depends principally on the degree
of beta cell dysfunction. Also anatomic changes imposed
by malabsorptive surgery can result in protein malnutri-
tion, vitamin and mineral deficiencies. Clinically signifi-
cant deficiencies in calcium; folic acid; iron; and vitamins D,
B<sub>12</sub>, A, and K are common. Thus, patients undergoing
malabsorptive procedures require lifelong supplementa-
tion and monitoring by a team familiar with possible
deficiencies. Both early and late dumping symptoms can
also occur.

Nonobese patients with type 2 diabetes frequently have
increased visceral adiposity—the so-called metabolically
obese normal weight patient. There is less emphasis on
weight loss, but exercise remains an important aspect of
treatment.

B. Glucose lowering agents—The current recom-
mandation is to start metformin therapy at diagnosis and not
wait to see whether the patient can achieve target glycemic
control with weight management and exercise. Metformin
is advantageous because, apart from lowering glucose
without the risk of hypoglycemia, it also lowers serum
triglycerides and promotes some modest weight loss. In the
UKPDS study, metformin use in the obese participants
was associated with reduction in risk of cardiovascular
events. The medication, however, cannot be used in patients
with end-stage renal disease, and sometimes gastrointestinal
side effects develop at even the lowest doses and persist
over time. Under these circumstances the choice of the
initial agent depends on a number of factors, including
comorbid conditions, adverse reactions to the medications,
ability of the patient to monitor for hypoglycemia, medica-
tion cost, and patient and clinician preferences. Sulfonylureas
have been available for many years and their
use in combination with metformin is well established.
They do, however, have the propensity of causing hypogly-
cemia and weight gain. Pioglitazone improves peripheral
insulin resistance and lowers glucose without causing
hypoglycemia. Troublesome adverse reactions include
weight gain, fluid retention and heart failure, increased
fracture risk in women, and possible increased risk of blad-
er cancer. Pioglitazone is contraindicated in patients with
active liver disease and in patients with liver enzymes ≥ 2.5
times the upper limit of normal. The α-glucosidase inhib-
itors have modest glucose lowering effects and have gastro-
intestinal side effects. The GLP-1 receptor agonists
(exenatide and liraglutide) have a lower risk of hypoglyce-
mia than the sulfonylureas and they promote weight loss.
However, they need to be given by injection, cause nausea,
may cause pancreatitis, and are contraindicated in patients
with gastroparesis. The **DPP-4 inhibitors** (sitagliptin and saxagliptin) also have a low risk of hypoglycemia, and they do not cause nausea or vomiting. They can also be used in patients with kidney impairment. There are, however, reports of serious allergic reactions, including anaphylaxis, angioedema, and Stevens-Johnson syndrome. There is also concern that they may, like the GLP-1 receptor agonists, cause pancreatitis.

When diabetes is not well controlled with initial therapy (usually metformin), then a second agent should be added. In patients who experience hyperglycemia after a carbohydrate-rich meal (such as dinner), a short-acting secretagogue before meals may suffice to get the glucose levels into the target range. Patients with severe insulin resistance may be candidates for pioglitazone. Patients who are very concerned about weight gain may benefit from a trial of GLP-1 receptor agonist or DPP-4 inhibitor. If two agents are inadequate, then a third agent is added, although data regarding efficacy of such combined therapy are limited.

When the combination of oral agents (and injectable GLP-1 receptor agonists) fail to achieve euglycemia in patients with type 2 diabetes, then insulin treatment should be instituted. Various insulin regimens may be effective. One proposed regimen is to continue the oral combination therapy and then simply add a bedtime dose of NPH or long-acting insulin analog (insulin glargine or insulin detemir) to reduce excessive nocturnal hepatic glucose output and improve fasting glucose levels. If the patient does not achieve target glucose levels during the day, then daytime insulin treatment can be initiated. A convenient insulin regimen under these circumstances is a split dose of 70/30 NPH/regular mixture (or Humalog Mix 75/25 or NovoLogMix 70/30) before breakfast and before dinner. If this regimen fails to achieve satisfactory glycemic goals or is associated with unacceptable frequency of hypoglycemic episodes, then a more intensive regimen of multiple insulin injections can be instituted as in patients with type 1 diabetes. Metformin principally reduces hepatic glucose output, and it is reasonable to continue with this medication when insulin therapy is instituted. Pioglitazone, which improves peripheral insulin sensitivity, can be used together with insulin but this combination is associated with more weight gain and peripheral edema. The sulfonylureas also continue to be of benefit. There is limited information on the benefits of continuing the GLP1-receptor agonists or the DPP-4 inhibitors once insulin therapy is initiated. Weight-reducing interventions should continue even after initiation of insulin therapy and may allow for simplification of the therapeutic regimen in the future.

**D. Acceptable Levels of Glycemic Control**

A reasonable aim of therapy is to approach normal glycemic excursions without provoking severe or frequent hypoglycemia. What has been considered “acceptable” control includes blood glucose levels of 90–130 mg/dL (5–7.2 mmol/L) before meals and after an overnight fast, and levels no higher than 180 mg/dL (10 mmol/L) 1 hour after meals and 150 mg/dL (8.3 mmol/L) 2 hours after meals. HbA1c levels < 7% are a reasonable goal for nonpregnant adults. Less stringent HbA1c goals may be appropriate in children, those with a history of severe hypoglycemia, limited life expectancy, and advanced microvascular and macrovascular disease. In the elderly frail patient, an HbA1c target of approximately 8% may be reasonable although formal evidence is lacking. It should be emphasized that the value of blood pressure control was as great or greater than glycemic control in type 2 patients as regards microvascular as well as macrovascular complications.

**E. Complications of Insulin Therapy**

1. **Hypoglycemia**—Hypoglycemic reactions are the most common complications that occur in patients with diabetest who are treated with insulin. Hypoglycemia may result from delay in taking a meal or from unusual physical exertion without supplemental calories or decrease in insulin dose. In addition, hypoglycemia can occur in patient taking sulfonylureas, repaglinide, and nateglinide, particularly if the patient is elderly, has kidney or liver disease, or is taking certain other medications that alter metabolism of the sulfonylureas (eg, phenylbutazone, sulfonamides, or warfarin). It occurs more frequently with the use of long-acting sulfonylureas than when shorter-acting agents are used.

The signs and symptoms of hypoglycemia may be divided into those resulting from stimulation of the autonomic nervous system and those from neuroglycopenia (insufficient glucose for normal central nervous system function). When the blood glucose falls to around 54 mg/dL (3 mmol/L), the patient starts to experience both sympathetic (tachycardia, palpitations, sweating, tremulousness) and parasympathetic (nausea, hunger) nervous system symptoms. If these autonomic symptoms are ignored and the glucose levels fall further (to around 50 mg/dL [2.8 mmol/L]), then neuroglycopenic symptoms appear, including irritability, confusion, blurred vision, tiredness, headache, and difficulty speaking. A further decline in glucose can then lead to loss of consciousness or even a seizure. With repeated episodes of hypoglycemia, there is...
adaptation, and autonomic symptoms do not occur until the blood glucose levels are much lower and so the first symptoms are often due to neuroglycopenia. This condition is referred to as “hypoglycemic unawareness.” It has been shown that hypoglycemic unawareness can be reversed by keeping glucose levels high for a period of several weeks. Except for sweating, most of the sympathetic symptoms of hypoglycemia are blunted in patients receiving β-blocking agents for angina pectoris or hypertension. Though not absolutely contraindicated, these medications must be used with caution in insulin-requiring diabetics, and β₁-selective blocking agents are preferred.

Hypoglycemia in insulin-treated patients with diabetes occurs as a consequence of three factors: behavioral issues, impaired counterregulatory systems, and complications of diabetes.

**Behavioral issues** include injecting too much insulin for the amount of carbohydrates ingested. Drinking alcohol in excess, especially on an empty stomach, can also cause hypoglycemia. In patients with type 1 diabetes, hypoglycemia can occur during or even several hours after exercise, and so glucose levels need to be monitored and food and insulin adjusted. Some patients do not like their glucose levels to be high, and they treat every high glucose level aggressively. These individuals who “stack” their insulin—that is, give another dose of insulin before the first injection has had its full action—can develop hypoglycemia.

**Counterregulatory issues** resulting in hypoglycemia include impaired glucagon response, sympatho-adrenal responses, and cortisol deficiency. Patients with diabetes of >5 years duration lose their glucagon response to hypoglycemia. As a result, they are at a significant disadvantage in protecting themselves against falling glucose levels. Once the glucagon response is lost, their sympatho-adrenal responses take on added importance. Unfortunately, aging, autonomic neuropathy, or hypoglycemic unawareness due to repeated low glucose levels further blunts the sympatho-adrenal responses. Occasionally, Addison disease develops in persons with type 1 diabetes mellitus; when this happens, insulin requirements fall significantly, and unless insulin dose is reduced, recurrent hypoglycemia will develop.

**Complications of diabetes** that increase the risk for hypoglycemia include autonomic neuropathy, gastroparesis, and end-stage chronic kidney disease. The sympathetic nervous system is an important system alerting the individual that the glucose level is falling by causing symptoms of tachycardia, palpitations, sweating, and tremulousness. Failure of the sympatho-adrenal responses increases the risk of hypoglycemia. In addition, in patients with gastroparesis, if insulin is given before a meal, the peak of insulin action may occur before the food is absorbed causing the glucose levels to fall. Finally, in end-stage chronic kidney disease, hypoglycemia can occur presumably because of decreased insulin clearance as well as loss of renal contribution to gluconeogenesis in the postabsorptive state.

To prevent and treat insulin-induced hypoglycemia, the diabetic patient should carry glucose tablets or juice at all times. For most episodes, ingestion of 15 grams of carbohydrate is sufficient to reverse the hypoglycemia. The patient should be instructed to check the blood glucose in 15 minutes and treat again if the glucose level is still low. A parenteral glucagon emergency kit (1 mg) should be provided to every patient with diabetes who is receiving insulin therapy. Family or friends should be instructed how to inject it subcutaneously or intramuscularly into the buttock, arm, or thigh in the event that the patient is unconscious or refuses food. The medication can occasionally cause vomiting, and the unconscious patient should be turned on his or her side to protect the airway. The glucagon mobilizes glycogen from the liver, raising the blood glucose by about 36 mg/dL (2 mmol/L) in about 15 minutes. After the patient recovers consciousness, additional oral carbohydrate should be given. People with diabetes receiving hypoglycemic medication therapy should also wear an identification MedicAlert bracelet or necklace or carry a card in his or her wallet. The telephone number for the MedicAlert Foundation International in Turlock, California, is 1-800-ID-ALERT and the Internet address is www.medicalert.org.

Medical personnel treating severe hypoglycemia can give 50 mL of 50% glucose solution by rapid intravenous infusion. If intravenous access is not available, 1 mg of glucagon can be injected intramuscularly.

2. **Immunopathology of insulin therapy**—At least five molecular classes of insulin antibodies are produced during the course of insulin therapy in diabetes, including IgA, IgD, IgE, IgG, and IgM. With the increased therapeutic use of purified pork and especially human insulin, the various immunopathologic syndromes such as insulin allergy, immune insulin resistance, and lipoatrophy have become quite rare since the titers and avidity of these induced antibodies are generally quite low.

A. **Insulin allergy**—Insulin allergy, or immediate-type hypersensitivity, is a rare condition in which local or systemic urticaria is due to histamine release from tissue mast cells sensitized by adherence of anti-insulin IgE antibodies. In severe cases, anaphylaxis results. When only human insulin has been used from the onset of insulin therapy, insulin allergy is exceedingly rare. Antihistamines, corticosteroids, and even desensitization may be required, especially for systemic hypersensitivity. There have been case reports of successful use of insulin lispro in those rare patients who have a generalized allergy to human insulin or insulin resistance due to a high titer of insulin antibodies.

B. **Immune insulin resistance**—A low titer of circulating IgG anti-insulin antibodies that neutralize the action of insulin to a small extent develops in most insulin-treated patients. With the old animal insulins, a high titer of circulating antibodies sometimes developed, resulting in extremely high insulin requirements—often more than 200 units daily. This is now rarely seen with the switch to highly purified pork or human insulins and has not been reported with the analogs.

C. **Lipoatrophies**—Atrophy of subcutaneous fatty tissue leading to disfiguring excavations and depressed areas may rarely occur at the site of injection. This complication results from an immune reaction, and it has become rarer with the development of pure and human insulin
preparations. Lipohypertrophy, on the other hand, is a consequence of the pharmacologic effects of insulin being deposited in the same location repeatedly. It can occur with purified insulins as well. Rotation of injection sites will prevent lipohypertrophy. There is a case report of a patient who had intractable lipohypertrophy with human insulin but no longer had the problem when he switched to insulin lispro.

#### Chronic Complications of Diabetes

Late clinical manifestations of diabetes mellitus include a number of pathologic changes that involve small and large blood vessels, cranial and peripheral nerves, the skin, and the lens of the eye. These lesions lead to hypertension, end-stage chronic kidney disease, blindness, autonomic and peripheral neuropathy, amputations of the lower extremities, myocardial infarction, and cerebrovascular accidents. These late manifestations correlate with the duration of the diabetic state subsequent to the onset of puberty. In type 1 diabetes, end-stage chronic kidney disease develops in up to 40% of patients, compared with < 20% of patients with type 2 diabetes. As regards proliferative retinopathy, it ultimately develops in both types of diabetes but has a slightly higher prevalence in type 1 patients (25% after 15 years’ duration). In patients with type 1 diabetes, complications from end-stage chronic kidney disease are a major cause of death, whereas patients with type 2 diabetes are more likely to have macrovascular diseases leading to myocardial infarction and stroke as the main causes of death. Cigarette use adds significantly to the risk of both microvascular and macrovascular complications in diabetic patients.

**A. Ocular Complications**

1. **Diabetic cataracts**—Premature cataracts occur in diabetic patients and seem to correlate with both the duration of diabetes and the severity of chronic hyperglycemia. Nonenzymatic glycosylation of lens protein is twice as high in diabetic patients as in age-matched nondiabetic persons and may contribute to the premature occurrence of cataracts.

2. **Diabetic retinopathy**—After 10 to 15 years, 25–50% of patients with type 1 diabetes show some signs of retinopathy. After 15 years, prevalence increases to 75–95%, and after 30 years, the prevalence approaches 100%. In patients with type 2 diabetes, the prevalence of nonproliferative retinopathy is 60% after 16 years.

There are two main categories of diabetic retinopathy: nonproliferative and proliferative. Diabetic macular edema can occur at any stage. **Nonproliferative ("background") retinopathy** represents the earliest stage of retinal involvement by diabetes and is characterized by such changes as microaneurysms, dot hemorrhages, exudates, and retinal edema. During this stage, the retinal capillaries leak proteins, lipids, or red cells into the retina. When this process occurs in the macula (clinically significant macular edema), the area of greatest concentration of visual cells, there is interference with visual acuity; this is the most common cause of visual impairment in patients with type 2 diabetes. **Proliferative retinopathy** involves the growth of new capillaries and fibrous tissue within the retina and into the vitreous chamber. It is a consequence of small vessel occlusion, which causes retinal hypoxia; this in turn stimulates new vessel growth. New vessel formation may occur at the optic disc or elsewhere on the retina. Proliferative retinopathy can occur in both types of diabetes but is more common in type 1, developing about 7–10 years after onset of symptoms, with a prevalence of 25% after 15 years’ duration. Prior to proliferation of new capillaries, a preproliferative phase often occurs in which arteriolar ischemia is manifested as cotton-wool spots (small infarcted areas of retina). Vision is usually normal until vitreous hemorrhage or retinal detachment occurs.

Proliferative retinopathy is a leading cause of blindness in the United States, particularly since it increases the risk of retinal detachment. Vision-threatening retinopathy virtually never appears in type 1 patients in the first 3–5 years of diabetes or before puberty. Up to 20% of patients with type 2 diabetes have retinopathy at the time of diagnosis. Annual consultation with an ophthalmologist should be arranged for patients who have had type 1 diabetes for more than 3–5 years and for all patients with type 2 diabetes, because many were probably diabetic for an extensive period of time before diagnosis. Patients with any macular edema, severe nonproliferative retinopathy, or any proliferative retinopathy require the care of an ophthalmologist. Extensive “scatter” xenon or argon photocoagulation and focal treatment of new vessels reduce severe visual loss in those cases in which proliferative retinopathy is associated with recent vitreous hemorrhages or in which extensive new vessels are located on or near the optic disk. Macular edema, which is more common than proliferative retinopathy in patients with type 2 diabetes (up to 20% prevalence), has a guarded prognosis, but it has also responded to scatter therapy with improvement in visual acuity if detected early. Injection of bevacizumab (Avastin), an anti-vascular endothelial growth factor (anti-VEGF), into the eye has been shown to stop the growth of the new blood vessels in diabetic eye disease. Avoiding tobacco use and correction of associated hypertension are important therapeutic measures in the management of diabetic retinopathy. There is no contraindication to using aspirin in patients with proliferative retinopathy.

3. **Glaucoma**—Glaucoma occurs in approximately 6% of persons with diabetes. It is responsive to the usual therapy for open-angle disease. Neovascularization of the iris in diabetics can predispose to closed-angle glaucoma, but this is relatively uncommon except after cataract extraction, when growth of new vessels has been known to progress rapidly, involving the angle of the iris and obstructing outflow.

**B. Diabetic Nephropathy**

As many as 4000 cases of end-stage chronic kidney disease occur each year among diabetic people in the United States. This is about one-third of all patients being treated for
end-stage chronic kidney disease and represents a considerable national health expense.

The cumulative incidence of nephropathy differs between the two major types of diabetes. Patients with type 1 diabetes have a 30–40% chance of having nephropathy after 20 years—in contrast to the much lower frequency in type 2 diabetes patients, in whom only about 15–20% develop chronic kidney disease. However, since there are many more individuals affected with type 2 diabetes, end-stage chronic kidney disease is much more prevalent in type 2 than in type 1 diabetes in the United States and especially throughout the rest of the world. Improved glycemic control and more effective therapeutic measures to correct hypertension—and with the beneficial effects of ACE inhibitors—can reduce the development of end-stage chronic kidney disease among diabetics.

Diabetic nephropathy is initially manifested by proteinuria; subsequently, as kidney function declines, urea and creatinine accumulate in the blood. Sensitive radioimmunoassay methods of detecting small amounts of urinary albumin have permitted detection of microgram concentrations—in contrast to the less sensitive dipstick strips, whose minimal detection limit is 0.3–0.5%. Conventional 24-hour urine collections, in addition to being inconvenient for patients, also show wide variability of albumin excretion, since several factors such as sustained erect posture, dietary protein, and exercise tend to increase albumin excretion rates. For these reasons, an albumin-creatinine ratio in an early morning spot urine collected upon awakening is preferable. In the early morning spot urine, a ratio of albumin (mg/L) to creatinine (mg/L) of < 30 mcg/mg creatinine is normal, and a ratio of 30–300 mcg/mg creatinine suggests abnormal microalbuminuria. At least two early morning spot urine collections over a 3- to 6-month period should be abnormal before a diagnosis of microalbuminuria is justified. Short-term hyperglycemia, exercise, urinary tract infections, heart failure, and acute febrile illness can cause transient albuminuria and so testing for microalbuminuria should be postponed until resolution of these problems.

Subsequent end-stage chronic kidney disease can be predicted by persistent urinary albumin excretion rates exceeding 30 mcg/min. Glycemic control as well as a low-protein diet (0.8 g/kg/d) may reduce both the hyperfiltration and the elevated microalbuminuria in patients in the early stages of diabetes and those with incipient diabetic nephropathy. Antihypertensive therapy also decreases microalbuminuria. Evidence from some studies—but not the UKPDS—supports a specific role for ACE inhibitors in reducing intraglomerular pressure in addition to their lowering of systemic hypertension. An ACE inhibitor (captopril, 50 mg twice daily) in normotensive diabetics impedes progression to proteinuria and prevents the increase in albumin excretion rate. Since microalbuminuria has been shown to correlate with elevated nocturnal systolic blood pressure, it is possible that “normotensive” diabetic patients with microalbuminuria have slightly elevated systolic blood pressure during sleep, which is lowered during antihypertensive therapy. This action may contribute to the reported efficacy of ACE inhibitors in reducing microalbuminuria in “normotensive” patients.

If treatment is inadequate, then the disease progresses with proteinuria of varying severity occasionally leading to nephrotic syndrome with hypoalbuminemia, edema, and an increase in circulating LDL cholesterol, as well as progressive azotemia. In contrast to all other kidney disorders, the proteinuria associated with diabetic nephropathy does not diminish with progressive end-stage chronic kidney disease (patients continue to excrete 10–11 g daily as creatinine clearance diminishes). As end-stage chronic kidney disease progresses, there is an elevation in the renal threshold at which glycosuria appears.

Patients with diabetic nephropathy should be evaluated and monitored by a nephrologist. There has been gradual improvement in quality of life of diabetic patients receiving dialysis. The cumulative survival for diabetic patients is about 22% compared with about 37% for dialysis patients without diabetes. Diabetic nephropathy accounts for about 20% of kidney transplantations performed annually in the United States. Survival rates have also improved for diabetic patients after kidney transplantation.

C. Diabetic Neuropathy

Diabetic neuropathies are the most common complications of diabetes affecting up to 50% of older patients with type 2 diabetes.

1. Peripheral neuropathy—

A. Distal symmetric polyneuropathy—This is the most common form of diabetic peripheral neuropathy where loss of function appears in a stocking-glove pattern and is due to an axonal neuropathic process. Longer nerves are especially vulnerable, hence the impact on the foot. Both motor and sensory nerve conduction is delayed in the peripheral nerves, and ankle jerks may be absent.

Sensory involvement usually occurs first and is generally bilateral, symmetric, and associated with dulled perception of vibration, pain, and temperature. The pain can range from mild discomfort to severe incapacitating symptoms (see below). The sensory deficit may eventually be of sufficient degree to prevent patients from feeling pain. Patients who have a sensory neuropathy should therefore be examined with a 5.07 Semmes Weinstein filament and those who cannot feel the filament must be considered at risk for unperceived neuropathic injury.

The denervation of the small muscles of the foot results in clawing of the toes and displacement of the submetatarsal fat pads anteriorly. These changes, together with the joint and connective tissue changes, alter the biomechanics of the foot and increase plantar pressures. This combination of decreased pain threshold, abnormally high foot pressures, and repetitive stress (such as from walking) can lead to calluses and ulcerations in the high-pressure areas such as over the metatarsal heads (Figure 27–4). Peripheral neuropathy, autonomic neuropathy, and trauma also predisposes to the development of Charcot arthropathy. An acute case of Charcot foot arthropathy presents with pain and swelling, and if left untreated, leads to a “rocker bottom” deformity and ulceration. The early radiologic changes show joint subluxation and periarticular fractures. As the
B. Isolated peripheral neuropathy—Involvement of the distribution of only one nerve (“mononeuropathy”) or of several nerves (“mononeuropathy multiplex”) is characterized by sudden onset with subsequent recovery of all or most of the function. This neuropathology has been attributed to vascular ischemia or traumatic damage. Cranial and femoral nerves are commonly involved, and motor abnormalities predominate. The patient with cranial nerve involvement usually has diplopia and single third, fourth, or sixth nerve weakness on examination but the pupil is spared. A full recovery of function occurs in 6–12 weeks. Diabetic amyotrophy presents with onset of severe pain in the front of the thigh. Within a few days or weeks of the onset of pain, weakness and wasting of the quadriceps develops. As the weakness appears, the pain tends to improve. Management includes analgesia and improved diabetes control. The symptoms improve over 6–18 months.

C. Painful diabetic neuropathy—Hypersensitivity to light touch and occasionally severe “burning” pain, particularly at night, can become physically and emotionally disabling. Amitriptyline, 25–75 mg at bedtime, has been recommended for pain associated with diabetic neuropathy. Dramatic relief has often resulted within 48–72 hours. This rapid response is in contrast to the 2 or 3 weeks required for an antidepressive effect. Patients often attribute the benefit to having a full night’s sleep. Mild to moderate morning drowsiness is a side effect that generally improves with time or can be lessened by giving the medication several hours before bedtime. This medication should not be continued if improvement has not occurred after 5 days of therapy. If amitriptyline’s anticholinergic effects are too troublesome, then nortriptyline can be used. Desipramine in doses of 25–150 mg/d seems to have the same efficacy as amitriptyline. Tricyclic antidepressants, in combination with the phenothiazine, fluphenazine, have been shown in two studies to be efficacious in painful neuropathy, with benefits unrelated to relief of depression. Gabapentin (900–1800 mg/d in three divided doses) has also been shown to be effective in the treatment of painful neuropathy and should be tried if the tricyclic medications prove ineffective. Pregabalin, a congener of gabapentin, has been shown in an 8-week study to be more effective than placebo in treating painful diabetic peripheral neuropathy. However, this medication was not compared with an active control. Also, because of its abuse potential, it has been categorized as a schedule V controlled substance. Duloxetine, a serotonin and norepinephrine reuptake inhibitor, has been approved for the treatment of painful diabetic neuropathy. In clinical trials, this medication reduced the pain sensitivity score by 40–50%. Capsaicin, a topical irritant, has been found to be effective in reducing local nerve pain; it is dispensed as a cream (Zostrix 0.025%, Zostrix-HP 0.075%) to be rubbed into the skin over the painful region two to four times daily. Gloves should be used for application since hand contamination could result in discomfort if the cream comes in contact with eyes or sensitive areas such as the genitalia.

process progresses, there is frank osteoclastic destruction leading to deranged and unstable joints particularly in the midfoot. Not surprisingly, the key issue for the healing of neuropathic ulcers in a foot with good vascular supply is mechanical unloading. In addition, any infection should be treated with debridement and appropriate antibiotics; healing duration of 8–10 weeks is typical. Occasionally, when healing appears refractory, platelet-derived growth factor (becaplermin [Regranex]) should be considered for local application. A post-marketing epidemiologic study showed increased cancer deaths in patients who had used three or more tubes of becaplermin on their leg or feet ulcers, and there is now a “black box” warning on the medication label. Once ulcers are healed, therapeutic footwear is key to preventing recurrences. Custom molded shoes are reserved for patients with significant foot deformities. Other patients with neuropathy may require accommodative insoles that distribute the load over as wide an area as possible. Patients with foot deformities and loss of their protective threshold should get regular care from a podiatrist. Patients should be educated on appropriate footwear and those with loss of their protective threshold should be instructed to inspect their feet daily for reddened areas, blisters, abrasions, or lacerations.
treatment of postherpetic neuralgia and is in clinical trials for the treatment of painful diabetic neuropathy.

Diabetic neuropathic cachexia is a syndrome characterized by a symmetric peripheral neuropathy associated with profound weight loss (up to 60% of total body weight) and painful dysesthesias affecting the proximal lower limbs, the hands, or the lower trunk. Treatment is usually with insulin and analgesics. The prognosis is generally good, and patients typically recover their baseline weight with resolution of the painful sensory symptoms within 1 year.

2. Autonomic neuropathy—Neuropathy of the autonomic system occurs principally in patients with diabetes of long duration. It affects many diverse visceral functions including blood pressure and pulse, gastrointestinal activity, bladder function, and erectile dysfunction. Treatment is directed specifically at each abnormality.

Involvement of the gastrointestinal system may be manifested by nausea, vomiting, postprandial fullness, reflux or dysphagia, constipation or diarrhea (or both), and fecal incontinence. Gastroparesis should be considered in type 1 diabetic patients in whom unexpected fluctuations and variability in their blood glucose levels develop after meals. Radioisotope studies show marked delay in gastric emptying. Metoclopramide has been of some help in treating diabetic gastroparesis. It is a dopaminergic antagonist that has central antiemetic effects as well as a cholinergic action to facilitate gastric emptying. It is given in a dose of 10 mg orally three or four times a day, 30 minutes before meals and at bedtime. Drowsiness, restlessness, fatigue, and lassitude are common adverse effects. Tardive dyskinesia and extrapyramidal effects can occur, especially when used for longer than 3 months, and the FDA has cautioned against the long-term use of metoclopramide.

Erythromycin appears to bind to motilin receptors in the stomach and has been found to improve gastric emptying over the short term in doses of 250 mg three times daily, but its effectiveness seems to diminish over time. Tegaserod (Zelnorm), the partial 5-HT4 agonist, has been withdrawn from the US market by the FDA, so it is no longer used for this indication. In selected patients, injections of botulinum toxin into the pylorus can reduce pylorus sphincter resistance and enhance gastric emptying. Gastric electrical stimulation has been reported to improve symptoms and quality of life indices in patients with gastroparesis refractory to pharmacologic therapy.

Diarrhea associated with autonomic neuropathy has occasionally responded to broad-spectrum antibiotic therapy, although it often undergoes spontaneous remission. Refractory diabetic diarrhea is often associated with impaired sphincter control and fecal incontinence. Therapy with loperamide, 4–8 mg daily, or diphenoxylate with atropine, two tablets up to four times a day, may provide relief. In more severe cases, tincture of paregoric or codeine (60 mg tablets) may be required to reduce the frequency of diarrhea with loperamide, 4–8 mg daily, or diphenoxylate with atropine, two tablets up to four times a day, may provide relief. In more severe cases, tincture of paregoric or codeine (60 mg tablets) may be required to reduce the frequency of diarrhea.
D. Cardiovascular Complications

1. Heart disease—Microangiopathy occurs in the heart and may explain the etiology of congestive cardiomyopathies in diabetic patients who do not have demonstrable coronary artery disease. More commonly, however, heart disease in patients with diabetes is due to coronary atherosclerosis. Myocardial infarction is three to five times more common in diabetic patients and is the leading cause of death in patients with type 2 diabetes. Cardiovascular disease risk is increased in patients with type 1 diabetes as well, although the absolute risk is lower than in patients with type 2 diabetes. Premenopausal women who normally have lower rates of coronary artery disease lose this protection once diabetes develops. The increased risk in patients with type 2 diabetes reflects the combination of hyperglycemia, hyperlipidemia, abnormalities of platelet adhesiveness, coagulation factors, hypertension, oxidative stress, and inflammation. Large intervention studies of risk factor reduction in diabetes are lacking, but it is reasonable to assume that reducing these risk factors would have a beneficial effect. Lowering LDL cholesterol reduces first events in patients without known coronary disease and secondary events in patients with known coronary disease. These intervention studies included some patients with diabetes, and the benefits of LDL cholesterol lowering was apparent in this group. The National Cholesterol Education Program clinical practice guidelines have designated diabetes as a cardiovascular risk factor to receive treatment with an ACE inhibitor. More clinical studies are needed to address the question of whether patients with type 2 diabetes who do not have cardiovascular disease or microalbuminuria would specifically benefit from ACE inhibitor treatment.

Aspirin at a dose of 81–325 mg daily has been shown to effectively inhibit thromboxane synthesis by platelets and is effective in reducing cardiovascular morbidity and mortality in patients who have a history of myocardial infarction or stroke (secondary prevention). It is unclear if aspirin prevents primary cardiovascular events in people with diabetes. The current recommendation is to give aspirin to people with diabetes who have a greater than 10% 10-year risk of cardiovascular events. Typically, this includes most diabetic men aged 50 years or older and diabetic women aged 60 years or older with one or more additional risk factors (smoking, hypertension, dyslipidemia, family history of premature cardiovascular disease, or albuminuria). Contraindications for aspirin therapy are patients with aspirin allergy, bleeding tendency, recent gastrointestinal bleeding, or active hepatic disease. The Early Treatment Diabetic Retinopathy Study (ETDRS) showed that aspirin does not influence the course of proliferative retinopathy. There was no statistically significant difference in the severity of vitreous/preretinal hemorrhages or their rate of resolution between the aspirin and placebo groups. Thus, it appears that there is no contraindication to aspirin use to achieve cardiovascular benefit in diabetic patients who have proliferative retinopathy.

2. Peripheral vascular disease—Atherosclerosis is markedly accelerated in the larger arteries. It is often diffuse, with localized enhancement in certain areas of turbulent blood flow, such as at the bifurcation of the aorta or other large vessels. Clinical manifestations of peripheral vascular disease include ischemia of the lower extremities, erectile dysfunction, and intestinal angina. The incidence of gangrene of the feet in diabetics is 30 times that in age-matched controls. The factors responsible for its development, in addition to peripheral vascular disease, are small vessel disease, peripheral neuropathy with loss of both pain sensation and neurogenic inflammatory responses, and secondary infection. In two-thirds of patients with ischemic gangrene, pedal pulses are not palpable. In the remaining one-third who have palpable pulses, reduced blood flow through these vessels can be demonstrated by plethysmographic or Doppler ultrasound examination. Prevention of foot injury is imperative. Agents that reduce peripheral blood flow such as...
tobacco and propranolol should be avoided. Control of other risk factors such as hypertension is essential. Cholesterol-lowering agents are useful as adjunctive therapy when early ischemic signs are detected and when dyslipidemia is present. Patients should be advised to seek immediate medical care if a diabetic foot ulcer develops. Improvement in peripheral blood flow with endarterectomy and bypass operations is possible in certain patients.

E. Skin and Mucous Membrane Complications

Chronic pyogenic infections of the skin may occur, especially in poorly controlled diabetic patients. Candidal infection can produce erythema and edema of intertriginous areas below the breasts, in the axillas, and between the fingers. It causes vulvovaginitis in women with chronically uncontrolled diabetes who have persistent glucosuria and is a frequent cause of pruritus. While antifungal creams containing miconazole or clotrimazole offer immediate relief, recurrence is frequent unless glucosuria is reduced.

In some patients with type 2 diabetes, poor glycemic control may cause a severe hypertriglycemia, which can present as eruptive cutaneous xanthomas and pancreatitis. The skin lesions appear as yellow morbilliform eruptions 2–5 mm in diameter with erythematous areolae. They occur on extensor surfaces (elbows, knees, buttocks) and disappear after triglyceride levels are reduced.

Necrobiosis lipoidica diabeticorum is usually located over the anterior surfaces of the legs or the dorsal surfaces of the ankles. They are oval or irregularly shaped plaques with demarcated borders and a glistening yellow surface and occur in women two to four times more frequently than in men. Pathologically, the lesions show degeneration of collagen, granulomatous inflammation of subcutaneous tissues and blood vessels, capillary basement membrane thickening and obliteration of vessel lumina. The condition is associated with type 1 diabetes, although it can occur in patients with type 2 diabetes, and also in patients without diabetes. First-line therapy includes topical and subcutaneous corticosteroids. Improving glycemic control may help the condition.

“Shin spots” are not uncommon in adult diabetics. They are brownish, rounded, painless atrophic lesions of the skin in the pretibial area.

F. Bone and Joint Complications

A number of bone and joint complications occur in people with diabetes. Long-standing diabetes can cause progressive stiffness of the hand secondary to contracture and thickening of skin over the joints (diabetic chiroarthropathy), frozen shoulder (adhesive capsulitis), carpal tunnel syndrome, and Dupuytren contractures. These complications are believed to be due to glycosylation of collagen and perhaps other proteins in connective tissue. There may also be an inflammatory component.

Data on bone mineral density and fracture risk in people with diabetes are contradictory. Patients with type 2 diabetes do appear to be at increased risk for nonvertebral fractures. Women with type 1 diabetes have an increased risk of fracture when compared with women without diabetes. Other factors, such as duration of diabetes, and diabetes complications, such as neuropathy and renal disease, likely affect both the bone mineral density and fracture risk.

Diffuse idiopathic skeletal hyperostosis (DISH) is characterized by ossification of the anterior longitudinal ligaments of the spine and various extraspinal ligaments. It causes stiffness and decreased range of spinal motion. The peripheral joints most commonly affected are the metacarpophalangeal joints, elbows, and shoulders. Diabetes, obesity, hypertension, and dyslipidemia are risk factors for this condition.

Hyperuricemia is more common in type 2 diabetes, so it is not surprising that these patients are at increased risk for acute and tophaceous gout.

Bursitis, particularly of the shoulders and hips occurs more frequently than expected in patients with diabetes.

insulin regimens in the hospital because patients are not eating as usual; they are often fasting for procedures; clinical events increase adverse reactions associated with diabetes medicines, eg, thiazolidinediones can cause fluid retention and worsen heart failure; metformin should not be used in patients with significant chronic kidney or liver disease, or those getting contrast for radiographic studies. Subcutaneous or intravenous insulin therapy is frequently substituted for other diabetes medicines because the insulin dose can be adjusted to match changing inpatient needs and it is safe to use insulin in patients with heart, kidney, and liver disease.

**Surgery** represents a stress situation during which most of the insulin antagonists (eg, catecholamines, growth hormone, and corticosteroids) are mobilized. In the diabetic patient, this can lead to a worsening of hyperglycemia and perhaps even ketoacidosis. The aim of medical management of people with diabetes during the perioperative period is to minimize these stress-induced changes. Recommendations for management depend both on the patient’s usual diabetic regimen and on the type of surgery (major or minor) to be done (see also Chapter 3).

For people with diabetes controlled with diet alone, no special precautions must be taken unless diabetic control is markedly disturbed by the procedure. If this occurs, small doses of short-acting insulin as needed will correct the hyperglycemia.

Patients taking oral agents should not take them on the day of surgery. If there is significant hyperglycemia, small doses of short-acting insulin are given as needed. If this approach does not provide adequate control, an insulin infusion should be started in the manner indicated below. The oral agents can be restarted once the patient is eating normally after the operation. It is important to order a postoperative serum creatinine level to ensure adequate kidney function prior to restarting metformin therapy.

Patients taking insulin represent the only serious challenge to management of diabetes when surgery is necessary. However, with careful attention to changes in the clinical or laboratory picture, glucose control can be managed successfully. The protocol used to control the glucose depends on the kind of diabetes (type 1 or type 2); whether it is minor surgery (lasting < 2 hours and patient eating afterwards) or major surgery (lasting > 2 hours, with invasion of a body cavity, and patient not eating afterwards); and the preoperative insulin regimen (basal bolus or premixed insulin twice a day or premeal bolus only or regular insulin before meals and NPH at bedtime). Patients with type 1 diabetes must be receiving some insulin to prevent the development of diabetic ketoacidosis. Many patients with type 2 diabetes who are taking insulin do well perioperatively without insulin for a few hours. Ideally, patients with diabetes should undergo surgery early in the morning. Table 27–12 summarizes the approach for these patients.

One insulin infusion method adds 10 units of regular insulin to 1 L of 5% dextrose in 0.45% saline, and this is infused intravenously at a rate of 100–180 mL/h. This gives the patient 1–1.8 units of insulin per hour which, except in the most severe cases, generally keeps the blood glucose within the range of 100–250 mg/dL (5.5–13.9 mmol/L). The infusion may be continued for several days, if necessary. Perioperatively, plasma glucose or blood glucose should be determined every 2–4 hours to be sure metabolic control is adequate. If it is not, adjustments in the ratio of insulin to dextrose in the intravenous solution can be made.

An alternative method, which is gaining increasing popularity, consists of separate infusions of insulin and glucose delivered by pumps to permit independent adjustments of each infusion rate, depending on hourly variation of blood glucose values. There are a number of different algorithms available for insulin infusions.

After surgery, when the patient has resumed an adequate oral intake, subcutaneous administration of insulin can be resumed and intravenous administration of insulin and dextrose can be stopped 30 minutes after the first subcutaneous dose. Insulin needs may vary in the first several days after surgery because of continuing postoperative stresses and because of variable caloric intake. In this situation, multiple doses of short-acting insulin plus some long-acting basal insulin, guided by blood glucose determinations, can keep the patient in acceptable metabolic control.

In the intensive care units (ICUs), glucose levels are controlled most frequently using insulin infusions. Patients receiving total parenteral nutrition can have insulin added to the bag. Standard total parenteral nutrition contains 25% dextrose so an infusion rate of 50 mL/h delivers 12.5 g of dextrose per hour.

| **Table 27–12.** Recommendations for management of insulin-treated diabetes during surgery. |
|-------------------------------------------------|-------------------------------------------------|-------------------------------------------------|
| **Type of Diabetes**                            | **Minor Surgical Procedures** (< 2 hours; eating afterwards)** | **Major surgical procedures (> 2 hours; invasion of body cavity; not eating immediately after recovery)** |
| Type 2: Patients taking basal bolus insulin regimen; twice daily premixed insulin | No insulin on the day of operation. Start 5% dextrose infusion; monitor fingerstick blood glucose and give subcutaneous short-acting insulin every 4 or 6 hours | Same regimen as minor procedure. If control is not satisfactory, then intravenous insulin infusion |
| Type 1: Patients taking basal bolus insulin regimen or using insulin pump | Patients using pump should discontinue the pump the evening before procedure and give 24 hour basal insulin. On day of procedure, start 5% dextrose; monitor blood glucose and give subcutaneous short-acting insulin every 4 or 6 hours | Initiate insulin infusion on morning of procedure and transition back to usual regimen when eating |

---

On the general surgical and medical wards, most patients are treated with subcutaneous insulin regimens. Limited cross-sectional and prospective studies suggest that the best glucose control is achieved on a combination of basal and bolus regimen with 50% of daily insulin needs provided by intermediate- or long-acting insulins. Standardized order sets prompt medical personnel to write more physiologic insulin orders; they can reduce errors; and they often include algorithms for recognition and treatment of hypoglycemia.

The morbidity and mortality in diabetic patients is twice that of nondiabetic patients. Those with new-onset hyperglycemia (ie, those without a prediagnosis of diabetes) have even higher mortality—almost eightfold that of nondiabetic patients in one study. These observations have led to the question of whether tight glycemic control in the hospital improves outcomes.

A prospective trial in surgical ICU patients (Leuven 1 study) reported that aggressive treatment of hyperglycemia (defined as blood glucose > 110 mg/dL [6.1 mmol/L]) reduced mortality and morbidity. Only a small number of persons in this study (204 of 1548) had a diagnosis of diabetes preoperatively, and so this study suggests that controlling hyperglycemia per se (independent of a diagnosis of diabetes) was beneficial. The benefits, however, were principally seen in patients who were in the ICU for longer than 5 days, and it is unclear whether the benefits also apply to most surgical patients who stay in the ICU for only 1 to 2 days.

The same investigators performed a similar prospective trial among 1200 medical ICU patients (Leuven 2 study) and reported that aggressive treatment of hyperglycemia reduced morbidity (decreased acquired kidney injury and increased early weaning from mechanical ventilation) but not mortality. Again, as in the surgical ICU study, only a small number of persons (16.9%) had a diagnosis of diabetes at admission.

The findings of the Leuven studies, however, have not been confirmed by other prospective studies. Two other ICU-based studies (Glucontrol and VISEP) that attempted to confirm the findings were unable to do so. Both studies were stopped prematurely, however. The Glucontrol study was stopped because an interim analysis (falsely) suggested increased mortality in the test group; and the VISEP study was stopped because of a seven-fold increase in hypoglycemic events in the intensively treated group. A large multicenter, multinational study (NICE-SUGAR) recruited 6104 surgical and medical ICU patients with hyperglycemia (20%) who had diabetes and randomized them to tight control (blood glucose levels of 81–108 mg/dL [4.5–6.0 mmol/L]) or less tight control (glucose levels < 180 mg/dL [< 10 mmol/L]). The tight group achieved blood glucose levels of 115 ± 18 mg/dL (6.4 ± 1.0 mmol/L) and the conventional group, 144 ± 23 mg/dL (8 ± 1.3 mmol/L). There were more deaths (829 versus 751 deaths) in the tight glucose control group compared with the less tight control group (P = .02). The excess deaths in the intensive group were due to cardiovascular events. The intensively treated group also had more cases of severe hypoglycemia (206 versus 15 cases).

A study on tight intraoperative glycemic control during cardiac surgery also failed to show any benefit; if anything, the intensively treated group had more events. The United Kingdom Glucose Insulin in Stroke Trial (GIST-UK) failed to show beneficial effect of tight glycemic control in stroke patients; however, the investigators acknowledged that, because of slow recruitment, the study was underpowered.

Thus, based on the evidence available so far, ICU patients with diabetes and new-onset hyperglycemia with blood glucose levels above 180 mg/dL (10 mmol/L) should be treated with insulin, aiming for target glucose levels between 140 mg/dL (7.8 mmol/L) and 180 mg/dL (10 mmol/L). In the ICU setting, aiming for blood glucose levels close to 100 mg/dL (5.6 mmol/L) is not beneficial and may even be harmful. When patients leave the ICU, target glucose values between 100 mg/dL (5.6 mmol/L) and 180 mg/dL (10 mmol/L) may be appropriate, although this view is based on clinical observations rather than conclusive evidence.

### B. Pregnancy and the Diabetic Patient

Tight glycemic control with normal HbA1c levels is very important during pregnancy. Early in pregnancy, poor control increases the risk of spontaneous abortion and congenital malformations. Late in pregnancy, poor control can result in polyhydramnios, preterm labor, stillbirth, and fetal macrosomia with its associated problems. Diabetes complications can impact both maternal and fetal health. Diabetic retinopathy can first develop during pregnancy or retinopathy that is already present can worsen. Diabetic women with microalbuminuria can have worsening albuminuria during pregnancy and are at higher risk for preclampsia. Patients who have preexistent kidney failure (prepregnancy creatinine clearance < 80 ml/min) are at high risk for further decline in kidney function during the pregnancy, and this may not reverse after delivery. Diabetic gastroparesis can severely exacerbate the nausea and vomiting of pregnancy and some patients may require fluid and nutritional support.

Although there is evidence that glyburide is safe during pregnancy, the current practice is to control diabetes with insulin therapy. Every effort should be made, utilizing multiple injections of insulin or a continuous infusion of insulin by pump, to maintain near-normalization of fasting and preprandial blood glucose values while avoiding hypoglycemia. The fast-acting insulin analogs insulin aspart and insulin lispro can be used, but data on using the long-acting insulin analogs is limited. A small study using insulin glargine in 32 pregnancies did not reveal any problems. There are no data on insulin detemir use in pregnancy. NPH is currently the preferred intermediate insulin for basal coverage during pregnancy.

Unless there are fetal or maternal complications, diabetic women should be able to carry the pregnancy to full-term, delivering at 38 to 41 weeks. Induction of labor before 39 weeks may be considered if there is concern about increasing fetal weight. See Chapter 19 for further details.
Prognosis

The DCCT showed that the previously poor prognosis for as many as 40% of patients with type 1 diabetes is markedly improved by optimal care. DCCT participants were generally young and highly motivated and were cared for in academic centers by skilled diabetes educators and endocrinologists who were able to provide more attention and services than are usually available. Improved training of primary care providers may be beneficial.

For type 2 diabetes, the UKPDS documented a reduction in microvascular disease with glycemic control, although this was not apparent in the obese subgroup. Cardiovascular outcomes were not improved by glycemic control, although antihypertensive therapy showed benefit in reducing the number of adverse cardiovascular complications as well as in reducing the occurrence of microvascular disease among hypertensive patients. In patients with visceral obesity, successful management of type 2 diabetes remains a major challenge in the attempt to achieve appropriate control of hyperglycemia, hypertension, and dyslipidemia. Once safe and effective methods are devised to prevent or manage obesity, the prognosis of type 2 diabetes with its high cardiovascular risks should improve considerably.

In addition to poorly understood genetic factors relating to differences in individual susceptibility to development of long-term complications of hyperglycemia, it is clear that in both types of diabetes, the diabetic patient’s intelligence, motivation, and awareness of the potential complications of the disease contribute significantly to the ultimate outcome.

When to Refer

- Patients with type 2 diabetes should be referred to an endocrinologist for comanagement with a primary care provider.
- Patients with type 2 diabetes should be referred to an endocrinologist if treatment goals are not met or if the patient requires an increasingly complex regimen to maintain glycemic control.
- Patients with type 2 diabetes should be referred to an ophthalmologist or optometrist for a dilated eye examination when the diabetes is diagnosed, and patients with type 1 diabetes should be referred 5 years after the diagnosis is made.
- Patients with peripheral neuropathy, especially those with loss of protective threshold (unable to detect 5.07 Semmes-Weinstein filament) or structural foot problems, should be referred to a podiatrist.
- Referrals to other specialists may be required for management of chronic complications of diabetes.

Coma may be due to a variety of causes not directly related to diabetes. Certain causes directly related to diabetes require differentiation: (1) Hypoglycemic coma resulting from excessive doses of insulin or oral hypoglycemic agents. (2) Hyperglycemic coma associated with either severe insulin deficiency (diabetic ketoacidosis) or mild to moderate insulin deficiency (hyperglycemic hyperosmolar state). (3) Lactic acidosis associated with diabetes, particularly in diabetics stricken with severe infections or with cardiovascular collapse.

Diabetic ketoacidosis may be the initial manifestation of type 1 diabetes or may result from increased insulin requirements in type 1 diabetes patients during the course of infection, trauma, myocardial infarction, or surgery. It is a life-threatening medical emergency with a mortality rate just under 5% in individuals under 40 years of age, but with a more serious prognosis in the elderly, who have mortality rates over 20%. The National Data Group reports an annual incidence of five to eight episodes of diabetic ketoacidosis per 1000 diabetic persons. Ketoacidosis may develop in patients with type 2 diabetes when severe stress such as sepsis or trauma is present. Diabetic ketoacidosis
has been found to be one of the more common serious complications of insulin pump therapy, occurring in approximately 1 per 80 patient-months of treatment. Many patients who monitor capillary blood glucose regularly ignore urine ketone measurements, which would signal the possibility of insulin leakage or pump failure before serious illness develops. Poor compliance, either for psychological reasons or because of inadequate education, is one of the most common causes of diabetic ketoacidosis, particularly when episodes are recurrent.

Clinical Findings

A. Symptoms and Signs

The appearance of diabetic ketoacidosis is usually preceded by a day or more of polyuria and polydipsia associated with marked fatigue, nausea, and vomiting. If untreated, mental stupor ensues that can progress to coma. Drowsiness is fairly common but frank coma only occurs in about 10% of patients. On physical examination, evidence of dehydration in a stuporous patient with rapid deep breathing and a “fruity” breath odor of acetone would strongly suggest the diagnosis. Hypotension with tachycardia indicates profound fluid and electrolyte depletion, and mild hypothermia is usually present. Abdominal pain and even tenderness may be present in the absence of abdominal disease. Conversely, cholecystitis or pancreatitis may occur with minimal symptoms and signs.

B. Laboratory Findings

(Table 27–13.) Typically, the patient with moderately severe diabetic ketoacidosis has a plasma glucose of 350–900 mg/dL (19.4–50 mmol/L), serum ketones at a dilution of 1:8 or greater, hyperkalemia (serum potassium level of 5–8 mEq/L), slight hyponatremia (serum sodium of approximately 130 mEq/L), hyperphosphatemia (serum phosphate level of 6–7 mg/dL [1.9–2.3 mmol/L]), and elevated blood urea nitrogen and serum creatinine levels. Acidosis may be severe (pH ranging from 6.9 to 7.2, and serum bicarbonate ranging from 5 mEq/L to 15 mEq/L); PCO₂ is low (15–20 mm Hg) related to hyperventilation. Fluid depletion is marked, typically about 100 mL/kg.

The hyperkalemia occurs despite total body potassium depletion because of the shift of potassium from the intracellular to extracellular spaces that occurs in systemic acidosis. The average total body potassium deficit resulting from osmotic diuresis, acidosis, and gastrointestinal losses is about 3–5 mEq/kg body weight. Similarly, despite the elevated serum phosphate, total body phosphate is generally depleted. Serum sodium is generally reduced due to loss of sodium ions (7–10 mEq/kg) by polyuria and vomiting and because severe hyperglycemia shifts intracellular water into the interstitial compartment. There is some controversy about the correction factor for the serum sodium in the presence of hyperglycemia. Many guidelines recommend a correction factor, whereby the serum sodium concentration decreases by 1.6 mEq/L for every 100 mg/dL (5.56 mmol/L) rise in plasma glucose above normal, but there is evidence that the decrease may be greater when patients have more severe hyperglycemia (greater than 400 mg/dL or 22.2 mmol/L) and/or volume depletion. One group has suggested (based on short-term exposure of normal volunteers to markedly elevated glucose levels) that, when the serum glucose is greater than 200 mg/dL (11.1 mmol/L), the serum sodium concentration decreases by at least 2.4 mEq/L. Serum osmolality can be directly measured by standard tests of freezing point depression or can be estimated by calculating the molarity of sodium, chloride, and glucose in the serum. A convenient method of estimating effective serum osmolality is as follows (normal values in humans are 280–300 mosm/kg):

\[
\text{mosm/kg} = 2 \left[ \text{measured Na}^{+} \right] + \frac{\text{Glucose (mg/dL)}}{18}
\]

These calculated estimates are usually 10–20 mosm/kg lower than values measured by standard cryoscopic techniques. Central nervous system depression or coma occurs when the effective serum osmolality exceeds 320–330 mosm/kg.

1Leftover urine in bladder might still contain glucose from earlier hyperglycemia.
2Alcohol can elevate plasma lactate as well as keto acids to reduce pH.
mosmy/L. Coma in a diabetic patient with a lower osmolality should prompt a search for cause of coma other than hyperosmolality (see Chapter 21).

Blood urea nitrogen and serum creatinine are invariably elevated because of dehydration. In some automated creatinine assays, serum creatinine can be falsely elevated by nonspecific chromogenicity of keto acids and glucose. Most laboratories, however, now routinely eliminate this interference.

Ketoacidemia represents the effect of insulin lack at multiple enzyme loci. Insulin lack associated with elevated levels of growth hormone, catecholamines, and glucagon contributes to increases in lipolysis from adipose tissue and in hepatic ketogenesis. In addition, reduced ketolysis by insulin–deficient peripheral tissues contributes to the ketoacidemia. The only true “keto” acid present is acetoacetic acid which, along with its by-product acetone, is measured by nitroprusside reagents (Acetest and Ketostix). The sensitivity for acetone, however, is poor, requiring over 10 mmol/L, which is seldom reached in the plasma of ketoacidotic patients—although this detectable concentration is readily achieved in urine. Thus, in the plasma of ketotic patients, only acetoacetate is measured by these reagents. The more prevalent β-hydroxybutyric acid has no ketone group and is therefore not detected by conventional nitroprusside tests. This takes on special importance in the presence of circulatory collapse during diabetic ketoacidosis, wherein an increase in lactate can shift the redox state to increase β-hydroxybutyric acid at the expense of the readily detectable acetoacetic acid. Bedside diagnostic reagents are then unreliable, suggesting no ketonemia in cases where β-hydroxybutyric acid is a major factor in producing the acidosis. A combined glucose and ketone meter (Precision Xtra, Abbott Diabetes Care) that is able to measure blood β-hydroxybutyrate concentration on capillary blood is now available. Many clinical laboratories also offer direct blood β-hydroxybutyrate measurement.

Elevation of serum amylase is common but often represents salivary as well as pancreatic amylase. Thus, in this setting, an elevated serum amylase is not specific for acute pancreatitis. Serum lipase may be useful if the diagnosis of acute pancreatitis is being seriously considered. Leukocytosis as high as 25,000/mcL with a left shift may occur with or without associated infection. The presence of an elevated or even a normal temperature would suggest the presence of an infection, since patients with diabetic ketoacidosis are generally hypothermic if uninfected.

### Treatment

Patients with mild diabetic ketoacidosis are alert and have pH levels between 7.25 and 7.30; those with moderate ketoacidosis have pH levels between 7.0 and 7.24 and are either alert or little drowsy; and those with severe ketoacidosis are stuporose and have a pH < 7.0. Those with mild ketoacidosis can be treated in the emergency department, but those with moderate or severe ketoacidosis require admission to the ICU or step-down unit. Therapeutic goals are to restore plasma volume and tissue perfusion, reduce blood glucose and osmolality toward normal, correct acidosis, replenish electrolyte losses, and identify and treat precipitating factors. Gastric intubation is recommended in the comatose patient to prevent vomiting and aspiration that may occur as a result of gastric atony, a common complication of diabetic ketoacidosis. An indwelling catheter may also be necessary. In patients with preexisting cardiac or renal failure or those in severe cardiovascular collapse, a central venous pressure catheter or a Swan-Ganz catheter should be inserted to evaluate the degree of hypovolemia and to monitor subsequent fluid administration.

A comprehensive flow sheet that includes vital signs, serial laboratory data, and therapeutic interventions (eg, fluids, insulin) should be meticulously maintained by the clinician responsible for the patient’s care. Plasma glucose should be recorded hourly and electrolytes and pH at least every 2–3 hours during the initial treatment period. Bedside glucose meters should be used to titrate the insulin therapy. The patient should not receive sedatives or opioids.

#### A. Fluid Replacement

In most patients, the fluid deficit is 4–5 L. Initially, 0.9% saline solution is the solution of choice to help reexpand the contracted vascular volume and should be started in the emergency department as soon as the diagnosis is established. The saline should be infused rapidly to provide 1 L/h over the first 1–2 hours. After the first 2 L of fluid have been given, the intravenous infusion should be at the rate of 300–400 mL/h. Use 0.9% (“normal”) saline unless the serum sodium is > 150 mEq/L, when 0.45% (“half normal”) saline solution should be used. The volume status should be very carefully monitored. Failure to give enough volume replacement (at least 3–4 L in 8 hours) to restore normal perfusion is one of the most serious therapeutic shortcomings adversely influencing satisfactory recovery. Excessive fluid replacement (more than 5 L in 8 hours) may contribute to acute respiratory distress syndrome or cerebral edema. When blood glucose falls to approximately 250 mg/dL (13.9 mmol/L), the fluids should be changed to a 5% glucose-containing solution to maintain serum glucose in the range of 250–300 mg/dL (13.9–16.7 mmol/L). This will prevent the development of hypoglycemia and will also reduce the likelihood of cerebral edema, which could result from too rapid decline of blood glucose.

#### B. Insulin Replacement

Immediately after initiation of fluid replacement, regular insulin should be given intravenously in a loading dose of 0.1 unit/kg as an intravenous bolus to prime the tissue insulin receptors. Following the initial bolus, intravenous doses of insulin as low as 0.1 unit/kg/h are continuously infused or given hourly as an intramuscular injection; this is sufficient to replace the insulin deficit in most patients. A recent prospective randomized study showed that a bolus dose is not required if patients are given hourly insulin infusion at 0.14 unit/kg. Replacement of insulin deficiency helps correct the acidosis by reducing the flux of fatty acids to the liver, reducing ketone production by the liver, and also improving removal of ketones from the blood. Insulin treatment

---

**CMDT 2013**

---
reduces the hyperosmolality by reducing the hyperglycemia. It accomplishes this by increasing removal of glucose through peripheral utilization as well as by decreasing production of glucose by the liver. This latter effect is accomplished by direct inhibition of gluconeogenesis and glycolysis as well as by lowered amino acid flux from muscle to liver and reduced hyperglucagonemia.

The insulin dose should be “piggy-backed” into the fluid line so the rate of fluid replacement can be changed without altering the insulin delivery rate. If the plasma glucose level fails to fall at least 10% in the first hour, a repeat loading dose (0.1 or 0.14 unit/kg) is recommended. The availability of bedside glucometers and of laboratory instruments for rapid and accurate glucose analysis (Beckman or Yellow Springs glucose analyzer) has contributed much to achieving optimal insulin replacement. Rarely, a patient with immune insulin resistance is encountered, and this requires doubling the insulin dose every 2–4 hours if hyperglycemia does not improve after the first two doses of insulin. The insulin dose should be adjusted to lower the glucose concentration by about 50–70 mg/dL (2.8–3.9 mmol/L).

C. Potassium

Total body potassium loss from polyuria and vomiting may be as high as 200 mEq. However, because of shifts of potassium from cells into the extracellular space as a consequence of acidosis, serum potassium is usually normal to slightly elevated prior to institution of treatment. As the acidosis is corrected, potassium flows back into the cells, and hypokalemia can develop if potassium replacement is not instituted. If the patient is not uremic and has an adequate urinary output, potassium chloride in doses of 10–30 mEq/h should be infused during the second and third hours after beginning therapy as soon as the acidosis starts to resolve. Replacement should be started sooner if the initial serum potassium is inappropriately normal or low and should be delayed if serum potassium fails to respond to initial therapy and remains above 5 mEq/L, as in cases of chronic kidney disease. Occasionally, a patient may present with a serum potassium level < 3.5 mEq/L, in which case insulin therapy should delayed until the potassium level is corrected to > 3.5 mEq/L. An ECG can be of help in monitoring the patient’s potassium status: High peaked T waves are a sign of hyperkalemia, and flattened T waves with U waves are a sign of hypokalemia. Foods high in potassium content should be prescribed when the patient has recovered sufficiently to take food orally. Tomato juice has 14 mEq of potassium per 240 mL, and a medium-sized banana provides about 10 mEq.

D. Sodium Bicarbonate

The use of sodium bicarbonate in management of diabetic ketoacidosis has been questioned since clinical benefit was not demonstrated in one prospective randomized trial and because of the following potentially harmful consequences: (1) development of hypokalemia from rapid shift of potassium into cells if the acidosis is overcorrected; (2) tissue anoxia from reduced dissociation of oxygen from hemoglobin when acidosis is rapidly reversed (leftward shift of the oxygen dissociation curve); and (3) cerebral acidosis resulting from lowering of cerebrospinal fluid pH. It must be emphasized, however, that these considerations are less important when very severe acidosis exists. Therefore, it is recommended that bicarbonate be administered to diabetic patients in ketoacidosis if the arterial blood pH is 7.0 or less, with careful monitoring to prevent overcorrection. One or two ampules of sodium bicarbonate (one ampule contains 44 mEq/50 mL) should be added to 1 L of 0.45% saline. (Note: Addition of sodium bicarbonate to 0.9% saline would produce a markedly hypertonic solution that could aggravate the hyperosmolar state already present.) This should be administered rapidly (over the first hour). It can be repeated until the arterial pH reaches 7.1, but it should not be given if the pH is 7.1 or greater since additional bicarbonate would increase the risk of rebound metabolic alkalosis as ketones are metabolized. Alkalosis shifts potassium from serum into cells, which could precipitate a fatal cardiac arrhythmia.

E. Phosphate

Phosphate replacement is seldom required in treating diabetic ketoacidosis. However, if severe hypophosphatemia of < 1 mg/dL (< 0.32 mmol/L) develops during insulin therapy, a small amount of phosphate can be replaced per hour as the potassium salt. Correction of hypophosphatemia helps restore the buffering capacity of the plasma, thereby facilitating renal excretion of hydrogen. It also corrects the impaired oxygen dissociation from hemoglobin by regenerating 2,3-diphosphoglycerate. However, three randomized studies in which phosphate was replaced in only half of a group of patients with diabetic ketoacidosis did not show any apparent clinical benefit from phosphate administration. Moreover, attempts to use potassium phosphate as the sole means of replacing potassium have led to a number of reported cases of severe hypokalemia with tetany. To minimize the risk of inducing tetany from too-rapid replacement of phosphate, the average deficit of 40–50 mmol of phosphate should be replaced intravenously at a rate no > 3–4 mmol/h in a 60–70-kg person. A stock solution (Abbott) provides a mixture of 1.12 g KH₂PO₄ and 1.18 g K₂HPO₄ in a 5-mL single-dose vial (this equals 22 mmol of potassium and 15 mmol of phosphate). One-half of this vial (25 mL) should be added to 1 L of either 0.45% saline or 5% dextrose in water. Two liters of this solution, infused at a rate of 400 mL/h, will correct the phosphate deficit at the optimal rate of 3 mmol/h while providing 4.4 mEq of potassium per hour. (Additional potassium should be administered as potassium chloride to provide a total of 10–30 mEq of potassium per hour, as noted above.) If the serum phosphate remains below 2.5 mg/dL (0.8 mmol/L) after this infusion, a repeat 5-hour infusion can be given.

F. Hyperchloremic Acidosis During Therapy

Because of the considerable loss of keto acids in the urine during the initial phase of therapy, substrate for subsequent regeneration of bicarbonate is lost and correction of the total bicarbonate deficit is hampered. A portion of the
bicarbonate deficit is replaced with chloride ions infused in large amounts as saline to correct the dehydration. In most patients, as the ketoacidosis clears during insulin replacement, a hyperchloremic, low-bicarbonate pattern emerges with a normal anion gap. This is a relatively benign condition that reverses itself over the subsequent 12–24 hours once intravenous saline is no longer being administered. Using a balanced electrolyte solution similar to serum in chloride concentration and pH during resuscitation instead of normal saline has been reported to prevent the hyperchloremic acidosis.

G. Treatment of Associated Infection
Antibiotics are prescribed as indicated. Cholecystitis and pyelonephritis may be particularly severe in these patients.

H. Transition to Subcutaneous Insulin Regimen
Once the diabetic ketoacidosis is controlled and the patient is awake and able to eat, subcutaneous insulin therapy can be initiated. The patient with type 1 diabetes may have persistent significant tissue insulin resistance and may require a total daily insulin dose of approximately 0.6 units/kg. The amount of insulin required in the previous 8 hours can also be helpful in estimating the initial insulin doses. Half the total daily dose can be given as a long-acting basal insulin and the other half as short-acting insulin premixes. The patient should receive subcutaneous basal insulin and rapid-acting insulin analog with the first meal and the insulin infusion discontinued an hour later. The overlap of the subcutaneous insulin action and insulin infusion is necessary to prevent relapse of the diabetic ketoacidosis. The increased insulin resistance is only present for a few days, and it is important to reduce both the basal and bolus insulins to avoid hypoglycemia. A patient with new-onset type 1 diabetes usually still has significant beta cell function and may not need any basal insulin and only very low doses of rapid-acting insulin before meals after recovery from the ketoacidosis. Patients with type 2 diabetes and diabetes ketoacidosis due to severe illness may initially require insulin therapy but can often transition back to oral agents during outpatient follow-up.

Prognosis
Low-dose insulin infusion and fluid and electrolyte replacement combined with careful monitoring of patients’ clinical and laboratory responses to therapy have dramatically reduced the mortality rates of diabetic ketoacidosis to < 5%. However, this complication remains a significant risk in the aged who have mortality rates > 20% and in patients in profound coma in whom treatment has been delayed. Acute myocardial infarction and infarction of the bowel following prolonged hypotension worsen the outlook. A serious prognostic sign is end-stage chronic kidney disease, and prior kidney dysfunction worsens the prognosis considerably because the kidney plays a key role in compensating for massive pH and electrolyte abnormalities. Symptomatic cerebral edema occurs primarily in the pediatric population. Risk factors for its development include severe baseline acidosis, rapid correction of hyperglycemia, and excess volume administration in the first 4 hours. Onset of headache or deterioration in mental status during treatment should lead to consideration of this complication. Intravenous mannitol at a dosage of 1–2 g/kg given over 15 minutes is the mainstay of treatment. Excess crystalloid infusion can precipitate pulmonary edema. Acute respiratory distress syndrome is a rare complication of treatment of diabetic ketoacidosis.

After recovery and stabilization, patients should be instructed on how to recognize the early symptoms and signs of ketoacidosis. Urine ketones or capillary blood β-hydroxybutyrate should be measured in patients with signs of infection or in insulin pump-treated patients when capillary blood glucose remains unexpectedly and persistently high. When ketonuria and glycosuria persist on several successive examinations, supplemental rapid acting insulin should be administered and liquid foods such as lightly salted tomato juice and broth should be ingested to replenish fluids and electrolytes. The patient should be instructed to contact the clinician if ketonuria persists, and especially if there is vomiting and inability to keep down fluids. Recurrent episodes of severe ketoacidosis often indicate poor compliance with the insulin regimen, and these patients will require intensive counseling.

even in older age groups. Lethargy and confusion develop as serum osmolality exceeds 310 mosm/kg, and coma can occur if osmolality exceeds 320–330 mosm/kg. Underlying chronic kidney disease or congestive heart failure is common, and the presence of either worsens the prognosis. A precipitating event such as infection, myocardial infarction, stroke, or recent operation is often present. Certain medications such as phenytoin, diazoxide, corticosteroids, and diuretics have been implicated in its pathogenesis, as have procedures associated with glucose loading such as peritoneal dialysis.

### Pathogenesis

A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization of muscle, fat, and liver while inducing hyperglucagonemia and increasing hepatic glucose output. With massive glycosuria, obligatory water loss ensues. If a patient is unable to maintain adequate fluid intake because of an associated acute or chronic illness or has suffered excessive fluid loss, marked dehydration results. As plasma volume contracts, chronic kidney disease develops, and the resultant limitation of renal glucose loss leads to increasingly higher blood glucose concentrations. Severe hyperosmolality develops that causes mental confusion and finally coma. It is not clear why ketosis is virtually absent under these conditions of insulin insufficiency, although reduced levels of growth hormone may be a factor, along with portal vein insulin concentrations sufficient to restrain ketogenesis.

### Clinical Findings

#### A. Symptoms and Signs

Onset may be insidious over a period of days or weeks, with weakness, polyuria, and polydipsia. The lack of features of ketoacidosis may retard recognition of the syndrome and delay therapy until dehydration becomes more profound than in ketoacidosis. Reduced intake of fluid is not an uncommon historical feature, due to either inappropriate lack of thirst, nausea, or inaccessibility of fluids to elderly, bedridden patients. Lethargy and confusion develop, progressing to convulsions and deep coma. Physical examination confirms the presence of profound dehydration in a lethargic or comatose patient without Kussmaul respirations.

#### B. Laboratory Findings

(Table 27–13.) Severe hyperglycemia is present, with blood glucose values ranging from 800 mg/dL to 2400 mg/dL (44.4 mmol/L to 133.2 mmol/L). In mild cases, where dehydration is less severe, dilutional hypernatremia as well as urinary sodium losses may reduce serum sodium to 120–125 mEq/L, which protects to some extent against extreme hyperosmolality. However, as dehydration progresses, serum sodium can exceed 140 mEq/L, producing serum osmolality readings of 330–440 mosm/kg. Ketosis and acidosis are usually absent or mild. Prerenal azotemia is the rule, with serum urea nitrogen elevations over 100 mg/dL (35.7 mmol/L) being typical.

### Treatment

#### A. Fluid Replacement

Fluid replacement is of paramount importance in treating nonketotic hyperglycemic coma. The onset of hyperosmolality is more insidious in elderly people without ketosis than in younger individuals with high serum ketone levels, which provide earlier indicators of severe illness (vomiting, rapid deep breathing, acetone odor, etc.). Consequently, diagnosis and treatment are often delayed until fluid deficit has reached levels of 6–10 L.

If hypovolemia is present as evidenced by hypotension and oliguria, fluid therapy should be initiated with 0.9% saline. In all other cases, 0.45% saline appears to be preferable as the initial replacement solution because the body fluids of these patients are markedly hyperosmolar. As much as 4–6 L of fluid may be required in the first 8–10 hours. Careful monitoring of the patient is required for proper sodium and water replacement. Once blood glucose reaches 250 mg/dL (13.9 mmol/L), fluid replacement should include 5% dextrose in either water, 0.45% saline solution, or 0.9% saline solution. The rate of dextrose infusion should be adjusted to maintain glycemic levels of 250–300 mg/dL (13.9–16.7 mmol/L) in order to reduce the risk of cerebral edema. An important end point of fluid therapy is to restore urinary output to 50 mL/h or more.

#### B. Insulin

Less insulin may be required to reduce the hyperglycemia in nonketotic patients as compared to those with diabetic ketoacidotic coma. In fact, fluid replacement alone can reduce hyperglycemia considerably by correcting the hypovolemia, which then increases both glomerular filtration and renal excretion of glucose. An initial insulin dose of 0.1 unit/kg is followed by an insulin infusion of 0.1 units/kg/h (or just an infusion of 0.14 units/kg/h without a bolus), which is titrated to lower blood glucose levels by 50–70 mg/dL per hour (2.8–3.9 mmol/L/h). Once the patient has stabilized and the blood glucose falls to around 250 mg/dL (13.9 mmol/L), insulin can be given subcutaneously.

#### C. Potassium

With the absence of acidosis, there may be no initial hypokalemia unless associated end-stage chronic kidney disease is present. This results in less severe total potassium depletion than in diabetic ketoacidosis, and less potassium replacement is therefore needed. However, because initial serum potassium is usually not elevated and because it declines rapidly as a result of insulin’s effect on driving potassium intracellularly, it has been recommended that potassium replacement be initiated earlier than in ketotic patients, assuming that no chronic kidney disease or oliguria is present. Potassium chloride (10 mEq/L) can be added to the initial bottle of fluids administered if the patient’s serum potassium is not elevated.

#### D. Phosphate

If severe hypophosphatemia (serum phosphate < 1 mg/dL [< 0.32 mmol/L]) develops during insulin therapy, phosphate
recovery can be given as described for ketoacidotic patients (at 3 mmol/l).

**Prognosis**

The severe dehydration and low output state may predispose the patient to complications such as myocardial infarction, stroke, pulmonary embolism, mesenteric vein thrombosis, and disseminated intravascular coagulation. Fluid replacement remains the primary approach to the prevention of these complications. Low-dose heparin prophylaxis is reasonable but benefits of routine anticoagulation remain doubtful. Rhabdomyolysis is a recognized complication and should be looked for and treated.

The overall mortality rate of hyperglycemic hyperosmolar state coma is more than ten times that of diabetic ketoacidosis, chiefly because of its higher incidence in older patients, who may have compromised cardiovascular systems or associated major illnesses and whose dehydration is often excessive because of delays in recognition and treatment. (When patients are matched for age, the prognoses of these two hyperglycemic emergencies are reasonably comparable.) When prompt therapy is instituted, the mortality rate can be reduced from nearly 50% to that related to the severity of coexistent disorders.

After the patient is stabilized, the appropriate form of long-term management of the diabetes must be determined. Insulin treatment should be continued for a few weeks but patients usually recover sufficient endogenous insulin secretion to make a trial of diet or diet plus oral agents worthwhile. When the episode occurs in a patient who has known diabetes, then education of the patient and caregivers should be instituted. They should be taught how to recognize situations (nausea and vomiting, infection) that predispose to recurrence of the hyperglycemic, hyperosmolar state, as well as detailed information on how to prevent the escalating dehydration that culminates in hyperosmolar coma (small sips of sugar-free liquids, increase in usual hypoglycemic therapy, or early contact with the clinician).

---

**General Considerations**

Lactic acidosis is characterized by accumulation of excess lactic acid in the blood. Normally, the principal sources of this acid are the erythrocytes (which lack enzymes for aerobic oxidation), skeletal muscle, skin, and brain. Conversion of lactic acid to glucose and its oxidation principally by the liver but also by the kidneys represent the chief pathways for its removal. Overproduction of lactic acid (tissue hypoxia), deficient removal (hepatic failure), or both (circulatory collapse) can cause accumulation. Lactic acidosis is not uncommon in any severely ill patient suffering from cardiac decompensation, respiratory or hepatic failure, septicemia, or infarction of bowel or extremities. With the discontinuance of phenformin therapy in the United States, lactic acidosis in patients with diabetes mellitus has become uncommon but occasionally occurs in metformin-treated patients (see above) and it still must be considered in the acidic diabetic, especially if the patient is seriously ill. Most cases of metformin-associated lactic acidosis occur in patients in whom there were contraindications to the use of metformin, in particular renal failure.

**Clinical Findings**

**A. Symptoms and Signs**

The main clinical feature of lactic acidosis is marked hyperventilation. When lactic acidosis is secondary to tissue hypoxia or vascular collapse, the clinical presentation is variable, being that of the prevailing catastrophic illness. However, in the idiopathic, or spontaneous, variety, the onset is rapid (usually over a few hours), blood pressure is normal, peripheral circulation is good, and there is no cyanosis.

**B. Laboratory Findings**

Plasma bicarbonate and blood pH are quite low, indicating the presence of severe metabolic acidosis. Ketones are usually absent from plasma and urine or at least not prominent. The first clue may be a high anion gap (serum sodium minus the sum of chloride and bicarbonate anions [in mEq/L] should be no > 15). A higher value indicates the existence of an abnormal compartment of anions. If this cannot be clinically explained by an excess of keto acids (diabetes), inorganic acids (uremia), or anions from medication overdosage (salicylates, methyl alcohol, ethylene glycol), then lactic acidosis is probably the correct diagnosis. (See also Chapter 21.) In the absence of azotemia, hyperphosphatemia may be a clue to the presence of lactic acidosis for reasons that are not clear. The diagnosis is confirmed by demonstrating, in a sample of blood that is promptly chilled and separated, a plasma lactic acid concentration of 5 mmol/L or higher (values as high as 30 mmol/L have been reported). Normal plasma values average 1 mmol/L, with a normal lactate/pyruvate ratio of 10:1. This ratio is greatly exceeded in lactic acidosis.¹

¹In collecting samples, it is essential to rapidly chill and separate the blood in order to remove red cells, whose continued glycolysis at room temperature is a common source of error in reports of high plasma lactate. Frozen plasma remains stable for subsequent assay.
Treatment

Aggressive treatment of the precipitating cause of lactic acidosis is the main component of therapy, such as ensuring adequate oxygenation and vascular perfusion of tissues. Empiric antibiotic coverage for sepsis should be given after culture samples are obtained in any patient in whom the cause of the lactic acidosis is not apparent.

Alkalization with intravenous sodium bicarbonate to keep the pH above 7.2 has been recommended by some in the emergency treatment of lactic acidosis, as much as 2000 mEq in 24 hours has been used. However, there is no evidence that the mortality rate is favorably affected by administering bicarbonate, and its use remains controversial. Hemodialysis may be useful in cases where large sodium loads are poorly tolerated and in cases associated with metformin toxicity.

Prognosis

The mortality rate of spontaneous lactic acidosis is high. The prognosis in most cases is that of the primary disorder that produced the lactic acidosis.

Differential Diagnosis (Table 27–14)

Fasting hypoglycemia may occur in certain endocrine disorders, such as hypopituitarism, Addison disease, or myxedema; in disorders related to liver malfunction, such as acute alcoholism or liver failure; and in instances of end-stage chronic kidney disease, particularly in patients requiring dialysis. These conditions are usually obvious, with hypoglycemia being only a secondary feature. When fasting hypoglycemia is a primary manifestation developing in adults without apparent endocrine disorders or inborn metabolic diseases from childhood, the principal diagnostic possibilities include: (1) hyperinsulinism, due to either pancreatic B cell tumors, iatrogenic or surreptitious administration of insulin or sulfonylureas and (2) hypoglycemia due to extrapancreatic tumors.

Postprandial (reactive) hypoglycemia may be seen after gastrointestinal surgery and is particularly associated with the dumping syndrome after gastrectomy and Roux-en-Y gastric bypass surgery. Occult diabetes very occasionally present with postprandial hypoglycemia. Rarely, it occurs with islet cell hyperplasia—the so-called noninsulinoma pancreatogenous hypoglycemia syndrome.

Alcohol-related hypoglycemia is due to hepatic glycogen depletion combined with alcohol-mediated inhibition of gluconeogenesis. It is most common in malnourished alcohol abusers but can occur in anyone who is unable to ingest food after an acute alcoholic episode followed by gastritis and vomiting.

Immunopathologic hypoglycemia is an extremely rare condition in which anti-insulin antibodies or antibodies to insulin receptors develop spontaneously. In the former case, the mechanism appears to relate to increasing dissociation of insulin from circulating pools of bound insulin. When antibodies to insulin receptors are found, most patients do not have hypoglycemia but rather severe insulin-resistant diabetes and acanthosis nigricans. However, during the course of the disease in these patients, certain anti-insulin receptor antibodies with agonist activity mimicking insulin action may develop, producing severe hypoglycemia.

1In the absence of clinically obvious endocrine, renal, or hepatic disorders and exclusive of diabetes mellitus treated with hypoglycemic agents.
Immediate recovery upon administration of glucose.
Blood glucose < 45 mg/dL (2.5 mmol/L) with a serum insulin level of 6 microunit/mL or more.

### General Considerations

Fasting hypoglycemia in an otherwise healthy, well-nourished adult is rare and is most commonly due to an adenoma of the islets of Langerhans. Ninety percent of such tumors are single and benign, but multiple adenomas can occur as well as malignant tumors with functional metastases. Adenomas may be familial, and multiple adenomas have been found in conjunction with tumors of the parathyroids and pituitary (MEN type 1 [MEN 1]). Over 99% of them are located within the pancreas and less than 1% in ectopic pancreatic tissue.

### Clinical Findings

#### A. Symptoms and Signs

The most important prerequisite to diagnosing an insulinoma is simply to consider it, particularly in relatively healthy-appearing persons who have fasting hypoglycemia associated with some degree of central nervous system dysfunction such as confusion or abnormal behavior. A delay in diagnosis can result in unnecessary treatment for psychomotor epilepsy or psychiatric disorders and may cause irreversible brain damage. In longstanding cases, obesity can result as a consequence of overeating to relieve symptoms.

The so-called Whipple triad is characteristic of hypoglycemia regardless of the cause. It consists of: (1) a history of hypoglycemic symptoms; (2) an associated fasting blood glucose of 45 mg/dL (2.5 mmol/L) or less; and (3) immediate recovery upon administration of glucose. The hypoglycemic symptoms in insulinoma often develop in the early morning or after missing a meal. Occasionally, they occur after exercise. They typically begin with evidence of central nervous system glucose lack and can include blurred vision or diplopia, headache, feelings of detachment, slurred speech, and weakness. Personality and mental changes vary from anxiety to psychotic behavior, and neurologic deterioration can result in convulsions or coma. Sweating and palpitations may not occur.

Hypoglycemic unawareness is very common in patients with insulinoma. They adapt to chronic hypoglycemia by increasing their efficiency in transporting glucose across the blood-brain barrier, which masks awareness that their blood glucose is approaching critically low levels. Counterregulatory hormonal responses as well as neurogenic symptoms such as tremor, sweating, and palpitations are therefore blunted during hypoglycemia. If lack of these warning symptoms prevents recognition of the need to eat to correct the problem, patients can lapse into severe hypoglycemic coma. However, symptoms and normal hormone responses during experimental insulin-induced hypoglycemia have been shown to be restored after successful surgical removal of the insulinoma. Presumably with return of euglycemia, adaptive effects on glucose transport into the brain are corrected, and thresholds of counterregulatory responses and neurogenic autonomic symptoms are therefore restored to normal.

#### B. Laboratory Findings

B cell adenomas do not reduce secretion in the presence of hypoglycemia, and the critical diagnostic test is to demonstrate inappropriately elevated serum insulin levels at a time when hypoglycemia is present. A reliable serum insulin level (radioimmunoassay) of 6 microunit/mL or more in the presence of blood glucose values below 45 mg/dL (2.5 mmol/L) is diagnostic of inappropriate hyperinsulinism (Table 27–15). Immunochemiluminometric assays (ICMA) have sensitivities of < 1 microunit/mL, and with these assays, the cutoffs for insulinomas is insulin level of 3 microunit/mL or higher. Other causes of hyperinsulinemic hypoglycemia must be considered, including factitious administration of insulin or sulfonylureas. Factitious use of insulin will result in suppression of endogenous insulin secretion and a low C-peptide levels. An elevated circulating proinsulin level in the presence of fasting hypoglycemia is characteristic of most B cell adenomas and does not occur in factitious hyperinsulinism. Thus, C-peptide and proinsulin levels (by ICMA) of > 200 pmol/L and > 5 pmol/L, respectively, are characteristic of insulinomas. In patients with insulinoma, plasma β-hydroxybutyrate levels are suppressed to 2.7 mmol/L or less.

In patients with epigastric distress, a history of renal calculi, or menstrual or erectile dysfunction, a serum calcium, gastrin, or prolactin level may be useful in screening for MEN 1 associated with insulinoma.

#### C. Diagnostic Tests

If the history is consistent with episodic spontaneous hypoglycemia, patients should be given a home blood glucose monitor and advised to monitor blood glucose levels at the time of symptoms and before consumption of carbohydrates, if this can be done safely. Patients with insulinomas frequently report fingerstick blood glucose levels between 40 mg/dL (2.2 mmol/L) and 50 mg/dL (2.8 mmol/L) at the time of symptoms. The diagnosis,
however, cannot be made based on a fingerstick blood glucose. It is necessary to have a low laboratory glucose concomitantly with elevated plasma insulin, proinsulin, and C-peptide levels and a negative sulfonylurea screen. When patients give a history of symptoms after only a short period of food withdrawal or with exercise, then an outpatient assessment can be attempted. The patient should be brought by a family member to the office after an overnight fast and observed in the office. Activity such as walking should be encouraged and fingerstick blood glucose measured repeatedly during observation. If symptoms occur or fingerstick blood glucose is below 50 mg/dL (2.8 mmol/L) then samples for plasma glucose, insulin, C-peptide, proinsulin, sulfonylurea screen, serum ketones, and antibodies to insulin should be sent. If outpatient observation does not result in symptoms or hypoglycemia and if the clinical suspicion remains high, then the patient should undergo an inpatient supervised 72-hour fast. A suggested protocol for the supervised fast is shown in Table 27–16.

In 30% of patients with insulinoma, the blood glucose levels often drop below 45 mg/dL (2.5 mmol/L) after an overnight fast, but some patients require up to 72 hours to develop symptomatic hypoglycemia. However, the term “72-hour fast” is actually a misnomer in most cases since the fast should be immediately terminated as soon as symptoms appear and laboratory confirmation of hypoglycemia is available. In normal male subjects, the blood glucose does not fall below 55–60 mg/dL (3.1–3.3 mmol/L) during a 3-day fast. In contrast, in normal premenopausal women who have fasted for only 24 hours, the plasma glucose may fall normally to such an extent that it can reach values as low as 35 mg/dL (1.9 mmol/L). In these cases, however, the women are not symptomatic, presumably owing to the development of sufficient ketonemia to supply energy needs to the brain. Insulinoma patients, on the other hand, become symptomatic when plasma glucose drops to subnormal levels, since inappropriate insulin secretion restricts ketone formation. Moreover, the demonstration of a nonsuppressed insulin level ≥ 6 microunit/mL using a RIA assay (> 3 microunit/mL using an ICMA assay) in the presence of hypoglycemia suggests the diagnosis of insulinoma. If hypoglycemia does not develop in a male patient after fasting for up to 72 hours—and particularly when this prolonged fast is terminated with a period of moderate exercise—inulinoma must be considered an unlikely diagnosis.

Stimulation with pancreatic B cell secretagogues such as tolbutamide, glucagon, or leucaen has been devised to demonstrate exaggerated and prolonged insulin secretion in the presence of insulinomas. However, because insulin-secreting tumors have a wide range of granule content and degrees of differentiation, they are variably responsive to these secretagogues; and a negative response does not necessarily rule out an insulinoma. For these reasons, stimulation tests are not recommended in the diagnostic work-up of insulinoma.

An oral glucose tolerance test is of no value in the diagnosis of insulin secreting tumors. HbA1c levels may be low but there is considerable overlap with normal patients and no particular value is diagnostic.

D. Preoperative Localization of B Cell Tumors

After the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings, studies to localize the tumor should be initiated. The focus of attention should be directed to the pancreas since that is where virtually all insulinomas originate.

Because of the small size of these tumors (averaging 1.5 cm in diameter in one large series), imaging studies do not necessarily identify all of them. A pancreatic dual phase helical CT scan with thin section can identify 82–94% of the lesions. MRI scans with gadolinium can be helpful in detecting a tumor in 85% of cases. One case report suggests that diffusion-weighted MRI can be useful for detecting and localizing small insulinomas, especially for those with no hypervascular pattern. The imaging study used will depend on local availability and local radiologic skill. If the imaging study is normal, then an endoscopic ultrasound should be performed. In experienced hands, about 80–90% of tumors can be detected with this procedure. Fine-needle aspiration of the identified lesion can be attempted to confirm the presence of a neuroendocrine tumor. If the tumor is not identified or the imaging result is equivocal, then the patient should undergo selective calcium-stimulated angiography, which has been reported to localize the tumor to a particular region of the pancreas approximately about 90% of the time. In this test, angiography is combined with injections of calcium gluconate into the gastroduodenal, splenic, and superior mesenteric arteries, and insulin levels are measured in the hepatic vein effluent. The procedure is performed after an overnight fast. Calcium gluconate 10% solution diluted to a volume of 5 mL with 0.93% saline is bolused into the selected artery at a dose of 0.0125 mmol

<td>(1) Obtain baseline serum glucose, insulin, proinsulin, and C-peptide measurements at onset of fast and place intravenous cannula.</td>
</tr>
<tr>
<td>(2) Permit only calorie-free and caffeine-free fluids and encourage supervised activity (such as walking).</td>
</tr>
<tr>
<td>(3) Measure urine for ketones at the beginning and every 12 hours and at end of fast.</td>
</tr>
<tr>
<td>(4) Obtain capillary glucose measurements with a reflectance meter every 4 hours until values &lt; 60 mg/dL are obtained. Then increase the frequency of fingersticks to each hour. When capillary glucose value is &lt; 49 mg/dL send a venous blood sample to the laboratory for serum glucose, insulin, proinsulin, and C-peptide measurements. Check frequently for manifestations of neuogycopeina.</td>
</tr>
<tr>
<td>(5) If symptoms of hypoglycemia occur or if a laboratory value of serum glucose is &lt; 45 mg/dL, or if 72 hours have elapsed then conclude the fast with a final blood sample for serum glucose, insulin, proinsulin, C-peptide, β-hydroxybutyrate and sulfonylu- rea measurements. Then give oral fast-acting carbohydrate followed by a meal. If the patient is confused or unable to take oral agents, then administer 50 mL of 50% dextrose intravenously over 3 to 5 minutes. Do not conclude a fast based simply on a capillary blood glucose measurement—wait for the laboratory glucose value—unless the patient is very symptomatic and it would be dangerous to wait.</td>
</tr>
</tbody>
</table>
calcium/kg (0.005 mmol calcium/kg for obese patients). Small samples of blood (5 mL) are taken from the hepatic effluent at times 0, 30, 60, 90, 120, and 180 seconds after the calcium injection. Fingerstick blood glucose levels are measured at intervals and a dextrose infusion is maintained throughout the procedure to prevent hypoglycemia. Calcium stimulates insulin release from insulinomas but not normal islets, and so a step-up from baseline in insulin levels at 30 or 60 seconds (twofold or greater) regionalizes the source of the hyperinsulinism to the head of the pancreas for the gastroduodenal artery, the uncinate process, and the body and tail of the pancreas for the splenic artery calcium infusions. A less than twofold elevation of insulin in the 120-second sample may represent effects of recirculating calcium and is not considered a positive localization. In a single insulinoma, the response is in one artery alone unless the tumor resides in an area fed by two arteries or if there are multiple insulinomas (eg, in MEN 1). Patients who have diffuse islet hyperplasia (the noninsulinoma pancreatogenous hypoglycemia syndrome) will have positive responses in multiple arteries. Because diazoxide may interfere with this test, it should be discontinued for at least 48–72 hours before sampling. Patients should be closely monitored during the procedure to avoid hypoglycemia (as well as hyperglycemia, which could affect insulin gradients). These studies combined with careful intraoperative ultrasonography and palpation by a surgeon experienced in insulinoma surgery identifies up to 98% of tumors.

### Treatment

The treatment of choice for insulin-secreting tumors is surgical resection. While waiting for surgery, patients should be given oral diazoxide. Divided doses of 300–400 mg/d usually suffice although an occasional patient may require up to 800 mg/d. Side effects include edema due to sodium retention, gastric irritation, and mild hirsutism. Hydrochlorothiazide, 25–50 mg daily, can be used to counteract the sodium retention and edema as well potentiate diazoxide’s hyperglycemic effect.

Tumor resection should be performed by a surgeon with previous experience in removing pancreatic B cell tumors. In patients with a single benign adenoma, 90–95% have a successful cure at the first surgical attempt when intraoperative ultrasound is used by a skilled surgeon. Diazoxide should be administered on the day of the surgery because it reduces the risk of hypoglycemia during surgery. Typically, it does not mask the glycemic rise indicative of surgical cure. Blood glucose should be monitored throughout surgery, and 5% or 10% dextrose infusion should be used to maintain euglycemia. In cases where the diagnosis has been established but no adenoma is located after careful palpation and use of intraoperative ultrasound, it is no longer advisable to blindly resect the body and tail of the pancreas, since a nonpalpable tumor missed by ultrasound is most likely embedded within the fleshy head of the pancreas that is left behind with subtotal resections. Most surgeons prefer to close the incision and schedule a selective arterial calcium stimulation with hepatic venous sampling to locate the tumor site prior to a repeat operation. Laparoscopy using ultrasound and enucleation has been successful with a single tumor of the body or tail of the pancreas, but open surgery remains necessary for tumors in the head of the pancreas.

In patients with inoperable functioning islet cell carcinoma and in approximately 5–10% of MEN 1 cases when subtotal removal of the pancreas has failed to produce cure, diazoxide is treatment of choice. Frequent carbohydrate feedings (every 2 to 3 hours) can also be helpful although weight gain may become a problem. If patients are unable to tolerate diazoxide because of gastrointestinal upset, hirsutism, or edema, the calcium channel blocker verapamil may be beneficial in view of its inhibitory effect on insulin release from insulinoma cells. Octreotide, a potent long-acting synthetic octapeptide analog of somatostatin, has been used to inhibit release of hormones from a number of endocrine tumors. A dose of 50 mcg of octreotide injected subcutaneously twice daily has been tried in cases where surgery failed to remove the source of hyperinsulinism. However, its effectiveness is limited since its affinity for somatostatin receptors of the pancreatic B cell is very much less than for those of the anterior pituitary somatotrophs for which it was originally designed as treatment for acromegaly. When hypoglycemia persists after attempted surgical removal of the insulinoma and if diazoxide or verapamil is poorly tolerated or ineffective, multiple small feedings may be the only recourse. Streptozocin can decrease insulin secretion in islet cell carcinomas and increase survival. With selective arterial administration, effective cytotoxic doses have been achieved without undue renal toxicity that characterized early experience. Benign tumors appear to respond poorly, if at all.

**NONISLET CELL TUMOR HYPOGLYCEMIA**

These rare causes of hypoglycemia include mesenchymal tumors such as retroperitoneal sarcomas, hepatocellular carcinomas, adrenocortical carcinomas, and miscellaneous epithelial-type tumors. The tumors are frequently large and readily palpated or visualized on CT scans or MRI.

In many cases the hypoglycemia is due to the expression and release of an incompletely processed insulin-like growth factor 2 (IGF-2) by the tumor. This immature form of the IGF-II molecule (pro-IGF-2 or “big IGF-2”) binds IGF-binding protein-3 (IGFBP-3) but not to the acid-labile subunit. As a consequence, this pro-IGF-II remains active and binds to insulin receptors in muscle to promote glucose transport and to insulin receptors in liver and kidney to reduce glucose output. It also binds to receptors for IGF-1.
in the pancreatic B cell to inhibit insulin secretion and in the pituitary to suppress growth hormone release. With the reduction of growth hormone, there is a consequent lowering of IGF-1 levels as well as IGFBP-3 and acid-labile subunit.

The diagnosis is supported by laboratory documentation of serum insulin levels below 5 microunit/mL with plasma glucose levels of 45 mg/dL (2.5 mmol/L) or lower. Values for growth hormone and IGF-1 are also decreased. Levels of IGF-2 may be increased but often are “normal” in quantity, despite the presence of the immature, higher-molecular-weight form of IGF-2, which can only be detected by special laboratory techniques.

Not all the patients with nonislet cell tumor hypoglycemia have elevated pro-IGF-II. Ectopic insulin production has been described in bronchial carcinoma, ovarian carcinoma, and small cell carcinoma of the cervix. Hypoglycemia due to Igf-1 released from a metastatic large cell carcinoma of the lung has also been reported.

The prognosis for these tumors is generally poor, and surgical removal should be attempted when feasible. Dietary management of the hypoglycemia is the mainstay of medical treatment, since diazoxide is usually ineffective.

POSTPRANDIAL HYPOGLYCEMIA

1. Hypoglycemia Following Gastric Surgery

Hypoglycemia sometimes develops in patients who have undergone gastric surgery (eg, gastrectomy, vagotomy, pyloroplasty, gastrojejunostomy, Nissan fundoplication, Billroth II procedure and Roux-en-Y), especially when they consume foods containing high levels of carbohydrates. This late dumping syndrome occurs about 1–3 hours after a meal and is a result of rapid delivery of high concentration of carbohydrates in the proximal small bowel and rapid absorption of glucose. The hyperinsulinemic response to the high carbohydrate load causes hypoglycemia. The symptoms include lightheadedness, sweating, confusion and even loss of consciousness after eating a high carbohydrate meal. It is possible that gastrointestinal hormones such as GLP-1 play a role in the hyperinsulinemic response. The incidence of secondary dumping syndrome declined with the advent of medical therapy for peptic ulcer disease. There has been resurgence of cases, however, with the popularity of Roux-en-Y gastric bypass surgery for the treatment of morbid obesity. Patients typically complain of symptoms that are more severe after consumption of large amounts of readily absorbable carbohydrates. In terms of documenting hypoglycemia, it is reasonable to request the patient to consume a meal that leads to symptoms during everyday life. An oral glucose tolerance test is not recommended because many normal persons have false-positive test results. There have been case reports of insulinoma and noninsulinoma pancreatogenous hypoglycemia syndrome in patients with hypoglycemia post Roux-en-Y surgery. It is unclear how often this occurs. A careful history may identify patients who have a history of hypoglycemia with exercise or meals, and these individuals may require a formal 72-hour fast to rule out an insulinoma.

Treatment for secondary dumping includes dietary modification, but this may be difficult to sustain. Patients can try more frequent meals with smaller portions of less rapidly digested carbohydrates. α-Glucosidase therapy may be a useful adjunct to a low carbohydrate diet. Octreotide 50 mcg administered subcutaneously two or three times a day 30 minutes prior to each meal has been reported to improve symptoms due to late dumping syndrome. Various surgical procedures to delay gastric emptying have been reported to improve symptoms but long-term efficacy studies are lacking.

2. Noninsulinoma Pancreatogenous Hypoglycemia Syndrome (Islet Cell Hyperplasia)

In a very small number of patients with organic hyperinsulinism, islet cell hyperplasia is present rather than an adenoma. This condition is referred to as noninsulinoma pancreatogenous hypoglycemia syndrome. These patients typically have documented hyperinsulinemic hypoglycemia after meals but not with fasting up to 72 hours. The patients have a positive response to calcium-stimulated angiography. A gradient-guided partial pancreatectomy leads to clinical remission, and the pathology of the pancreas shows evidence of islet cell hyperplasia and nesidioblastosis. These patients do not have mutations in the pancreatic islet beta-cell ATP-sensitive potassium channel inward rectifier (Kir 6.2) and the sulfonylurea receptor-1 (SUR1) genes, which have been reported in children with familial hyperinsulinemic hypoglycemia.

3. Functional Alimentary Hypoglycemia

Patients have symptoms suggestive of increased sympathetic activity, including anxiety, weakness, tremor, sweating or palpitations after meals. Physical examination and laboratory tests are normal. Previously, many of these patients underwent a 5-hour oral glucose tolerance test and the detection of glucose levels in the 50–60 mg/dL (2.8–3.3 mmol/L) range was thought to be responsible for the symptoms; the recommended treatment was dietary modification. It is now recognized that at least 10% of normal patients who do not have any symptoms have nadir glucose levels < 50 mg/dL (2.8 mmol/L) during a 4- to 6-hour oral glucose tolerance test. In a study comparing responses to oral glucose tolerance test with a mixed meal test, none of the patients who had plasma glucose levels < 50 mg/dL on oral glucose had low glucose values with the mixed meal. Thus, it is not recommended that these patients with symptoms suggestive of increased sympathetic activity undergo either a prolonged oral glucose tolerance test or a mixed meal test. Instead, the patients should be given home blood glucose monitors (with memories) and instructed to monitor fingerstick glucose levels at the time of symptoms. Only patients who have symptoms when
their fingerstick blood glucose is low (< 50 mg/dL) and who have resolution of symptoms when the glucose is raised by eating rapidly released carbohydrate need additional evaluation. Patients who do not have evidence for low glucose levels at time of symptoms are generally reassured by their findings. Counseling and support should be the mainstays in therapy, with dietary manipulation only an adjunct.

4. Occult Diabetes

This condition is characterized by a delay in early insulin release from pancreatic B cells, resulting in initial exaggeration of hyperglycemia during a glucose tolerance test. In response to this hyperglycemia, an exaggerated insulin release produces a late hypoglycemia 4–5 hours after ingestion of glucose. These patients are often obese and frequently have a family history of diabetes mellitus.

Patients with this type of postprandial hypoglycemia often respond to reduced intake of refined sugars with multiple, spaced, small feedings high in dietary fiber. In the obese, treatment is directed at weight reduction to achieve ideal weight. These patients should be considered to have prediabetes or early diabetes (type 1 or 2) and advised to have periodic medical evaluations.

5. Autoimmune Hypoglycemia

Patients with autoimmune hypoglycemia have early postprandial hyperglycemia followed by hypoglycemia 3–4 hours later. The hypoglycemia is attributed to a dissociation of insulin-antibody immune complexes, releasing free insulin.

The disorder is associated with methimazole treatment for Graves disease, although it can also occur in patients treated with various other sulhydryl-containing medications (captopril, penicillamine) as well as other drugs such as hydralazine, isoniazid, and procainamide. In addition, it has been reported in patients with autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, and polymyositis as well as in multiple myeloma and other plasma cell dyscrasias where paraproteins or antibodies cross-react with insulin. There is also an association with the HLA class II alleles (DRB1*0406, DQA1*0301, and DQB1*0302). These alleles are 10 to 20 times more common in Japanese and Korean populations, which explains why the disorder has been reported mostly in Japanese patients.

High titers of insulin autoantibodies, usually IgG class, can be detected. Insulin, proinsulin, and C-peptide levels may be elevated, but the results may be erroneous because of the interference of the insulin antibodies with the immunoassays for these peptides.

In most cases, the hypoglycemia is transient and usually resolves spontaneously within 3–6 months of diagnosis, particularly when the offending medications are stopped. The most consistent therapeutic benefit in management of this syndrome has been achieved by dietary treatment with small, frequent low-carbohydrate meals. Prednisone (30–60 mg orally daily) has been used to lower the titer of insulin antibodies.

FACTITIOUS HYPOGLYCEMIA

Factitious hypoglycemia may be difficult to document. A suspicion of self-induced hypoglycemia is supported when the patient is associated with the health professions or has access to insulin or sulfonylurea medications taken by a diabetic member of the family. The triad of hypoglycemia, high immunoreactive insulin, and suppressed plasma C peptide immunoreactivity is pathognomonic of exogenous insulin administration. Demonstration of circulating insulin antibodies supports this diagnosis in suspected cases. When sulfonylureas, repaglinide and nateglinide are suspected as a cause of factitious hypoglycemia, a plasma level of these medications to detect their presence may be required to distinguish laboratory findings from those of insulinoma.

HYPOGLYCEMIA DUE TO INSULIN RECEPTOR ANTIBODIES

Hypoglycemia due to insulin receptor autoantibodies is also an extremely rare syndrome; most cases have occurred in women often with a history of autoimmune disease. Almost all of these patients have also had episodes of insulin-resistant diabetes and acanthosis nigricans. Their hypoglycemia may be either fasting or postprandial and is often severe and is attributed to an agonistic action of the antibody on the insulin receptor. Balance between the antagonistic and agonistic effects of the antibodies determines whether insulin-resistant diabetes or hypoglycemia occurs. Hypoglycemia was found to respond to corticosteroid therapy but not to plasmapheresis or immunosuppression.

MEDICATION-INDUCED HYPOGLYCEMIA

A number of medications apart from the sulfonylureas can occasionally cause hypoglycemia. Common offenders

Methimazole, hydralazine, isoniazid, and procainamide are examples.
include the fluoroquinolones such as gatifloxacin and levofloxacin, pentamidine, quinine, ACE inhibitors, salicylates and β-adrenergic blocking agents. The fluoroquinolones, particularly gatifloxacin, has been associated with both hypoglycemia and hyperglycemia. It is thought that the drug acts on the ATP sensitive potassium channels in the beta cell. Hypoglycemia is an early event, and hyperglycemia occurs several days into therapy. Intravenous pentamidine is cytotoxic to beta cells and causes acute hyperinsulinemia and hypoglycemia followed by insulinopenia and hyperglycemia. Fasting patients taking non-cardioselective β-blockers can have an exaggerated hypoglycemic response to starvation. The β-blockade inhibits fatty acids and gluconeogenesis substrate release and reduces plasma glucagon response. Therapy with ACE inhibitors increases the risk of hypoglycemia in patients who are taking insulin or sulfonylureas presumably because these drugs increase sensitivity to circulating insulin by increasing blood flow to the muscle.

Ethanol-associated hypoglycemia may be due to hepatic depletion of NADH and altered NADH:NAD+ ratio. This in turn limits conversion of lactate to pyruvate, the main substrate for hepatic gluconeogenesis. With prolonged starvation, glycogen reserves become depleted within 18–24 hours and hepatic glucose output becomes totally dependent on gluconeogenesis. Under these circumstances, a blood concentration of ethanol as low as 45 mg/dL (9.8 mmol/L) can induce profound hypoglycemia by blocking gluconeogenesis. Neuroglycopenia in a patient whose breath smells of alcohol may be mistaken for alcoholic stupor. Prevention consists of adequate food intake during ethanol ingestion. Therapy consists of glucose administration to replenish glycogen stores until gluconeogenesis resumes.

When sugar-containing soft drinks are used as mixers to dilute alcohol in beverages (gin and tonic, rum and cola), there seems to be a greater insulin release than when the soft drink alone is ingested and a tendency for more of a late hypoglycemic overswing to occur 3–4 hours later. Prevention would consist of avoiding sugar mixers while ingesting alcohol and ensuring supplementary food intake to provide sustained absorption.

For patients with known cardiovascular disease (secondary prevention), cholesterol lowering leads to a consistent reduction in total mortality and recurrent cardiovascular events in men and women and in middle-aged and older patients. Among patients without cardiovascular disease (primary prevention), the data are less conclusive, with rates of cardiovascular events, heart disease mortality, and all-cause mortality differing among studies. Nonetheless, treatment algorithms have been designed to assist clinicians in selecting patients for cholesterol-lowering therapy based on their lipid levels and their overall risk of developing cardiovascular disease.

**Lipoproteins & Atherogenesis**

The plaques in the arterial walls of patients with atherosclerosis contain large amounts of cholesterol. The higher the level of low-density lipoproteins (LDL) cholesterol, the greater the risk of atherosclerotic heart disease; conversely, the higher the high-density lipoproteins (HDL) cholesterol, the lower the risk of coronary heart disease (CHD). This is true in men and women, in different racial and ethnic groups, and at all ages up to age 75 years. Because most cholesterol in serum is LDL, high total cholesterol levels are also associated with an increased risk of CHD. Middle-aged men whose serum cholesterol levels are in the highest quintile for age (above about 230 mg/dL or 5.95 mmol/L) have a risk of coronary death before age 65 years of about 10%; men in the lowest quintile (below about 170 mg/dL or 4.40 mmol/L) have a 3% risk. Death from CHD before age 65 years is less common in women, with equivalent risks one-third those of men. In men, each 10-mg/dL or 0.26-mmol/L increase in cholesterol (or LDL cholesterol) increases the risk of CHD by about 10%; each 5-mg/dL or 0.13-mmol/L increase in HDL reduces the risk by about 10%. The effect of HDL cholesterol is greater in women, whereas the effects of total and LDL cholesterol are smaller.

There are several genetic disorders that provide insight into the pathogenesis of lipid-related diseases. **Familial hypercholesterolemia**, rare in the homozygous state (about one per million) is a condition in which the cell-surface receptors for the LDL molecule are absent or defective, resulting in unregulated synthesis of LDL. Patients with two abnormal genes (homozygotes) have extremely high levels—up to eight times normal—and present with atherosclerotic disease in childhood. Homozygotes may require liver transplantation to correct their severe lipid abnormalities. Those with one defective gene (heterozygotes) have LDL concentrations twice normal; persons with this condition may develop CHD in their 30s or 40s.

Another rare condition is caused by an abnormality of lipoprotein lipase, the enzyme that enables peripheral tissues to take up triglyceride from chylomicrons and very-low-density lipoproteins (VLDL) particles. Patients with this condition, one cause of **familial hyperchylomicronemia**, have marked hypertriglyceridemia with recurrent pancreatitis and hepatosplenomegaly in childhood.

Numerous other genetic abnormalities of lipid metabolism are named for the abnormality noted when serum is electrophoresed (eg, dysbetalipoproteinemia) or from combinations of lipid abnormalities in families (eg, familial combined hyperlipidemia). Thus, family members of patients with severe lipid disorders are appropriately studied. Other patients have abnormalities in the production of apoproteins, such as increased apoprotein B and its affiliated lipoproteins, LDL and VLDL; reduced apoprotein AII and its affiliated particle; or excess lipoprotein(a). Other mutations occur in lipoprotein lipase and in the gene encoding for cholesterol efflux regulatory protein. Genome-wide association studies have identified additional genetic variants responsible for differences in serum lipids.

### When to Refer

- Known genetic lipid disorders.
- Striking family history of hyperlipidemia or premature atherosclerosis.
- Extremely high serum LDL cholesterol or triglyceride, or extremely low serum HDL cholesterol.

LIPID FRACTIONS & THE RISK OF CORONARY HEART DISEASE

In fasting serum, cholesterol is carried primarily on three different lipoproteins—the VLDL, LDL, and HDL molecules. Total cholesterol equals the sum of these three components:

\[
\text{Total cholesterol} = \text{HDL cholesterol} + \text{VLDL cholesterol} + \text{LDL cholesterol}
\]

Most clinical laboratories measure the total cholesterol, the total triglycerides, and the amount of cholesterol found in the HDL fraction, which is easily precipitated from serum. Most triglyceride is found in VLDL particles, which contain five times as much triglyceride by weight as cholesterol. The amount of cholesterol found in the VLDL fraction can be estimated by dividing the triglyceride by 5:

\[
\text{VLDL cholesterol} = \frac{\text{Triglycerides}}{5}
\]

Because the triglyceride level is used as a proxy for the amount of VLDL, this formula works only in fasting samples and when the triglyceride level is <400 mg/dL or <4.52 mmol/L. At higher triglyceride levels, LDL and VLDL cholesterol levels can be determined after ultracentrifugation or by direct chemical measurement.

The total cholesterol is reasonably stable over time; however, measurements of HDL and especially triglycerides may vary considerably because of analytic error in the laboratory and biologic variation in a patient’s lipid level. Thus, the LDL should always be estimated as the mean of at least two determinations; if those two estimates differ by more than 10%, a third lipid profile is obtained. The LDL is estimated as follows:

\[
\text{LDL cholesterol} = \text{Total cholesterol} - \text{HDL cholesterol} - \frac{\text{Triglycerides}}{5}
\]

When using SI units, the formula becomes

\[
\text{LDL cholesterol} = \text{Total cholesterol} - \text{HDL cholesterol} - \frac{\text{Triglycerides}}{2.2}
\]

Understanding the relationships of the different lipid fractions leads to a more accurate understanding of a patient’s lipid-related coronary risk than the total cholesterol. Two persons with the same total cholesterol of 275 mg/dL (7.11 mmol/L) may have very different lipid profiles. One may have an HDL cholesterol of 110 mg/dL (2.84 mmol/L) with a triglyceride of 150 mg/dL (1.69 mmol/L), giving an estimated LDL cholesterol of 135 mg/dL (3.49 mmol/L); the other may have an HDL cholesterol of 25 mg/dL (0.65 mmol/L) with a triglyceride of 200 mg/dL (2.26 mmol/L) and an LDL cholesterol of 210 mg/dL (5.43 mmol/L). The second would have more than a tenfold higher CHD risk than the first, assuming no differences in other factors. Because of high HDL cholesterol levels in women, many with apparently high total cholesterol levels have favorable lipid profiles. Thus, evaluation of the lipid fractions is essential before therapy is initiated.

Some authorities use the ratio of the total to HDL cholesterol as an indicator of lipid-related coronary risk: the lower this ratio is, the better. Although ratios are useful predictors within populations of patients, they may obscure important information in individual patients. (A total cholesterol of 300 mg/dL [7.76 mmol/L] and an HDL of 60 mg/dL [1.56 mmol/L] result in the same ratio as a total cholesterol of 150 mg/dL [3.88 mmol/L] with an HDL of 30 mg/dL [0.78 mmol/L].) Moreover, the total cholesterol-to-HDL cholesterol ratio will magnify the importance of variations in HDL measurement.

There is no true “normal” range for serum lipids. In Western populations, cholesterol values are about 20% higher than in Asian populations and exceed 300 mg/dL (7.76 mmol/L) in nearly 5% of adults. About 10% of adults have LDL cholesterol levels above 200 mg/dL (5.17 mmol/L). Total and LDL cholesterol levels tend to rise with age in persons who are otherwise in good health.

Declines are seen in acute illness, and lipid studies in such patients are of little value with the exception of the serum triglyceride level in a patient with pancreatitis. Cholesterol levels (even when expressed as an age-matched percentile rank, such as the highest 20%) do not remain constant over time, especially from childhood through adolescence and young adulthood. Thus, children and young adults with relatively high cholesterol may have lower levels later in life, whereas those with low cholesterol may show increases.

THERAPEUTIC EFFECTS OF LOWERING CHOLESTEROL

Reducing cholesterol levels in healthy middle-aged men without CHD (primary prevention) reduces their risk in proportion to the reduction in LDL cholesterol and the increase in HDL cholesterol. Treated patients have statistically significant and clinically important reductions in the rates of myocardial infarctions, new cases of angina, and need for coronary artery bypass procedures. The West of Scotland Study showed a 31% decrease in myocardial infarctions in middle-aged men treated with pravastatin compared with placebo. The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) study showed similar results with lovastatin. As with any
primary prevention interventions, large numbers of healthy patients need to be treated to prevent a single event. The numbers of patients needed to treat (NNT) to prevent a nonfatal myocardial infarction or a coronary artery disease death in these two studies were 46 and 50, respectively. The Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) study of atorvastatin in subjects with hypertension and other risk factors but without CHD also demonstrated a convincing 36% reduction in CHD events. The justification for the use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) showed a 44% reduction in a combined end point of myocardial infarction, stroke, revascularization, hospitalization for unstable angina, or death from cardiovascular causes. The NNT for 1 year to prevent one event was 169.

**Primary prevention studies** have found a less consistent effect on total mortality. The West of Scotland study found a 20% decrease in total mortality, tending toward statistical significance. The AFCAPS/TexCAPS study with lovastatin showed no difference in total mortality. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) also showed no reduction either in all-cause mortality or in CHD events when pravastatin was compared with usual care. Subjects treated with atorvastatin in the ASCOT study had a 13% reduction in mortality, but the result was not statistically significant. This study, however, was stopped early due to the marked reduction in CHD events. The JUPITER trial demonstrated a statistically significant 20% reduction in death from any cause. The NNT for 1 year was 400.

**In patients with CHD,** the benefits of cholesterol lowering are clearer. Major studies with statins have shown significant reductions in cardiovascular events, cardiovascular deaths, and all-cause mortality in men and women with coronary artery disease. The NNT to prevent a nonfatal myocardial infarction or a coronary artery disease death in these three studies were between 12 and 34. Aggressive cholesterol lowering with these agents causes regression of atherosclerotic plaques in some patients, reduces the progression of atherosclerosis in saphenous vein grafts, and can slow or reverse carotid artery atherosclerosis. Meta-analysis suggests that this latter effect results in a significant decrease in strokes. Results with other classes of medications have been less consistent. For example, gemfibrozil treatment subjects had fewer cardiovascular events, but there was no benefit in all-cause mortality when compared with placebo.

The disparities in results between primary and secondary prevention studies highlight several important points. The benefits and adverse effects of cholesterol lowering may be specific to each type of drug; the clinician cannot assume that the effects will generalize to other classes of medication. Second, the net benefits from cholesterol lowering depend on the underlying risk of CHD and of other disease. In patients with atherosclerosis, morbidity and mortality rates associated with CHD are high, and measures that reduce it are more likely to be beneficial even if they have no effect—or even slightly harmful effects—on other diseases.

---

**SECONDARY CONDITIONS THAT AFFECT LIPID METABOLISM**

Several factors, including drugs, can influence serum lipids (Table 28–1). These are important for two reasons: abnormal lipid levels (or changes in lipid levels) may be the presenting sign of some of these conditions, and correction of the underlying condition may obviate the need to treat an apparent lipid disorder. Diabetes and alcohol use, in particular, are commonly associated with high triglyceride levels that decline with improvements in glycemic control or reduction in alcohol use, respectively. Thus, secondary causes of high blood lipids should be considered in each patient with a lipid disorder before lipid-lowering therapy is started. In most instances, special testing is not needed: a history and physical examination are sufficient. However, screening for hypothyroidism in patients with hyperlipidemia is cost effective.

**CLINICAL PRESENTATIONS**

Most patients with high cholesterol levels have no specific symptoms or signs. The vast majority of patients with lipid abnormalities are detected by the laboratory, either as part of the workup of a patient with cardiovascular disease or as part of a preventive screening strategy. Extremely high levels of chylomicrons or VLDL particles (triglyceride level above 1000 mg/dL or 10 mmol/L) result in the formation of eruptive xanthomas (Figure 28–1) (red-yellow papules, especially on the buttocks). High LDL concentrations result in tendinous xanthomas on certain tendons (Achilles,
Such xanthomas usually indicate one of the underlying genetic hyperlipidemias. Lipemia retinalis (cream-colored blood vessels in the fundus) is seen with extremely high triglyceride levels (above 2000 mg/dL or 20 mmol/L).

**SCREENING FOR HIGH BLOOD CHOLESTEROL**

All patients with CHD or CHD risk equivalents (other clinical forms of atherosclerosis such as peripheral artery disease, abdominal aortic aneurysm, and symptomatic carotid artery disease; patients with diabetes mellitus; and patients with multiple risk factors that confer a >20% 10-year risk for developing CHD [Table 28–2]) should be screened for elevated lipids. The only exceptions are patients in whom lipid lowering is not indicated or desirable for other reasons. Patients who already have evidence of atherosclerosis are the group at highest risk of suffering additional manifestations in the near term and thus have the most to gain from reduction of blood lipids. Additional risk reduction measures for atherosclerosis are discussed in Chapter 10; lipid lowering should be just one aspect of a program to reduce the progression and effects of the disease.

In patients with cardiovascular disease, a complete lipid profile (total cholesterol, HDL cholesterol, and triglyceride levels) after an overnight fast should be obtained as a screening test. Those whose estimated LDL cholesterol level is high should have at least one repeat measurement. Specific treatments for high LDL cholesterol levels are discussed below. The goal of therapy should be to reduce the LDL cholesterol to below 100 mg/dL (2.59 mmol/L) or optimally to below 70 mg/dL (1.81 mmol/L). Evidence suggests that treatment with a statin is effective even if the starting LDL cholesterol is below 100 mg/dL (2.59 mmol/L). These data suggest that most patients with CHD or CHD risk equivalents should be treated with statin therapy.

The best screening and treatment strategy for adults who do not have atherosclerotic cardiovascular disease is less clear. Several algorithms have been developed to guide the clinician in treatment decisions, but management decisions are individualized based on the patient’s risk.

Although the National Cholesterol Education Program (NCEP) recommends screening of all adults aged 20 years or older for high blood cholesterol, the United States Preventive Services Task Force (USPSTF) suggests beginning at age 20 years only if there is increased risk of CHD. For men without increased risk, screening is recommended beginning at age 35 years. For women and for men aged 20 to 35 without increased risk, the USPSTF makes no recommendation for or against routine screening for lipid disorders. Although there is no established interval for screening, screening can be repeated every 5 years for those with average or low risk and more often for those whose levels are close to therapeutic thresholds. This strategy focuses cholesterol screening on those at the greatest risk of coronary artery disease and increases the cost effectiveness of cholesterol screening.

Individuals without cardiovascular disease can then be stratified according to risk factors as defined by the NCEP. Those with two or more risk factors are considered

(continued)
measuring total cholesterol alone, (2) measuring total cholesterol and HDL cholesterol, or (3) measuring LDL and HDL cholesterol. Each is acceptable, but treatment decisions are based on the LDL and HDL cholesterol levels. Measurement of the total cholesterol alone is the least expensive strategy and is adequate for low-risk individuals; those with total cholesterol > 200 mg/dL (> 6.0 mmol/L) should then be reevaluated with a fasting LDL and HDL cholesterol measurement. Measurement of the total cholesterol and HDL cholesterol allows for better characterization of the risk factor profile but also requires reevaluation if the total cholesterol is > 200 mg/dL (> 5.17 mmol/L) as recommended by the USPSTF. Initial measurement of the LDL and HDL cholesterol is least likely to lead to patient misinformation and misclassification and is the strategy recommended by the NCEP. Treatment decisions are based on the LDL cholesterol, and the patient’s risk factor profile (including the HDL cholesterol level) and estimated 10-year risk. Patients in the intermediate-risk group (two or more risk factors) are selected for diet therapy (therapeutic lifestyle changes) if LDL cholesterol is > 130 mg/dL (> 3.36 mmol/L). If the 10-year risk of CHD is < 10%, drug treatment is recommended if LDL is > 160 mg/dL (> 4.14 mmol/L); if the 10-year CHD risk is between 10% and 20%, drug treatment is recommended if LDL is > 130 mg/dL (> 3.36 mmol/L). Low-risk individuals with one or no risk factors and estimated 10-year CHD risk < 10% are selected for diet therapy if LDL cholesterol is > 160 mg/dL (> 4.14 mmol/L) and for drug therapy if it is > 190 mg/dL (> 4.91 mmol/L) (Table 28–3).

</table>

¹When LDL-lowering drug therapy is used, it is advised that intensity of therapy be sufficient to achieve at least a 30-40% reduction in LDL cholesterol levels.
²CHD includes history of myocardial infarction, unstable angina, coronary artery procedures (angioplasty or bypass surgery), or evidence of clinically significant myocardial ischemia.
³CHD risk equivalents include clinical manifestations of noncoronary forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and carotid artery disease [transient ischemic attacks or stroke of carotid origin with >50% obstruction of a carotid artery]), diabetes mellitus, and ≥ 2 risk factors with 10-year risk for CHD > 20%.
⁴Very high risk favors the optional LDL cholesterol goal of <70 mg/dL, or in patients with high triglycerides, non-high density lipoprotein (HDL) cholesterol < 100 mg/dL.
⁵Any person at high risk or moderately high risk who has lifestyle-related risk factors (eg, obesity, physical inactivity, elevated triglyceride, low HDL cholesterol, or metabolic syndrome) is a candidate for therapeutic lifestyle changes to modify these risk factors regardless of LDL cholesterol.
⁶If baseline LDL cholesterol is < 100 mg/dL, institution of an LDL-lowering drug is a therapeutic option on the basis of available clinical trial results. If a high-risk person has high triglycerides or low HDL cholesterol, combining a fibrate or nicotinic acid with an LDL-lowering drug can be considered.
⁷Risk factors include cigarette smoking, hypertension (blood pressure ≥ 140/90 mm Hg or an antihypertensive medication), low HDL cholesterol (<40 mg/dL), family history of premature CHD (CHD in male first-degree relative < 55 years of age, and age (men < 45 years; women ≥ 55 years).
⁸Electronic 10-year risk calculators are available at www.nhlbi.nih.gov/guidelines/cholesterol.
⁹Optional LDL cholesterol goal < 100 mg/dL.
¹⁰For moderately high-risk persons, when the LDL cholesterol level is 100-129 mg/dL at baseline or on lifestyle therapy, initiation of an LDL-lowering drug to achieve an LDL cholesterol level < 100 mg/dL is a therapeutic option on the basis of available clinical trial results.
¹¹Almost all people with zero or one risk factor have a 10-year CHD risk < 10%, and 10-year risk assessment in these people is thus not necessary.

LDL, low-density lipoprotein; NCEP, National Cholesterol Education Program; CHD, coronary heart disease.

Screening in Women

The foregoing screening and treatment guidelines, based largely on LDL cholesterol levels, are designed for both men and women. Yet several observational studies suggest that a low HDL cholesterol is a more important risk factor for CHD in women than a high LDL cholesterol. Meta-analysis of studies including women with known heart disease, however, has found that medications that primarily lower LDL cholesterol do prevent recurrent myocardial infarctions in women. There is insufficient evidence to be certain of a similar effect from LDL-lowering therapy in women without evidence of CHD. Although most experts recommend application of the same primary prevention guidelines for women as for men, clinicians should be aware of the uncertainty in this area. Using estimates of 10-year CHD risk may be particularly helpful in women since a larger percentage of women than men will have estimated 10-year CHD risks below 10% per year and thus women are less likely to benefit from therapy unless their LDL cholesterol is extremely high (>190 mg/dL or 4.91 mmol/L).

Screening in Older Patients

Meta-analysis of evidence relating cholesterol to CHD in the elderly suggests that cholesterol is not a risk factor for CHD for persons over age 75 years. Clinical trials have rarely included such individuals. One exception is the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER). In this study, elderly patients with cardiovascular disease (secondary prevention) benefited from statin therapy, whereas those without cardiovascular disease (primary prevention) did not. Although the NCEP recommends continuing treatment in the elderly, many clinicians will prefer to stop screening and treatment in patients age
75 years or older who do not have CHD. In patients age 75 years or older who have CHD, LDL-lowering therapy can be continued as recommended for younger patients with the disease. Decisions to discontinue therapy should be based on overall functional status and life expectancy, comorbidities, and patient preference and should be made in context with overall therapeutic goals and end-of-life decisions.

**TREATMENT OF HIGH LOW-DENSITY LIPOPROTEIN CHOLESTEROL**

Reduction of LDL cholesterol is just one part of a program to reduce the risk of cardiovascular disease. Other measures—including smoking cessation, hypertension control, and aspirin—are also of central importance. Less well studied but of potential value is raising the HDL cholesterol level. Quitting smoking reduces the effect of other cardiovascular risk factors (such as a high cholesterol level); it may also increase the HDL cholesterol level. Exercise (and weight loss) may reduce the LDL cholesterol and increase the HDL. Several studies have suggested that this approach may also be associated with reductions in endothelial dysfunction, insulin resistance, and markers of vascular inflammation and may result in better resolution of the metabolic syndrome than traditional cholesterol-lowering diets.

**Diet Therapy**

Studies of nonhospitalized adults have reported only modest cholesterol-lowering benefits of dietary therapy, typically in the range of a 5–10% decrease in LDL cholesterol, with even less in the long term. The effect of diet therapy, however, varies considerably among individuals, as some patients will have striking reductions in LDL cholesterol—up to a 25–30% decrease—but others will have clinically important increases. Thus, the results of diet therapy should be assessed about 4 weeks after initiation.

Cholesterol-lowering diets may also have a variable effect on lipid fractions. Diets very low in total fat or in saturated fat may lower HDL cholesterol as much as LDL cholesterol. It is not known how these diet-induced changes affect coronary risk.

Several nutritional approaches to diet therapy are available. Most Americans currently eat over 35% of calories as fat, of which 15% is saturated fat. Dietary cholesterol intake averages 400 mg/d. A cholesterol-lowering diet recommends reducing total fat to 25–30% and saturated fat to <7% of calories. Dietary cholesterol should be limited to <200 mg/d.

These diets replace fat, particularly saturated fat, with carbohydrate. In most instances, this approach will also result in fewer total calories consumed and will facilitate weight loss in overweight patients. Other diet plans, including the Dean Ornish Diet, the Pritikin Diet, and most vegetarian diets, restrict fat even further. Low-fat, high-carbohydrate diets may, however, result in reductions in HDL cholesterol.

An alternative strategy is the “Mediterranean diet,” which maintains total fat at approximately 35–40% of total calories but replaces saturated fat with monounsaturated fat such as that found in canola oil and in olives, peanuts, avocados, and their oils. This diet is equally effective at lowering LDL cholesterol but is less likely to lead to reductions in HDL cholesterol. Several studies have suggested that this approach may also be associated with reductions in endothelial dysfunction, insulin resistance, and markers of vascular inflammation and may result in better resolution of the metabolic syndrome than traditional cholesterol-lowering diets.

Other dietary changes may also result in beneficial changes in blood lipids. Soluble fiber, such as that found in oat bran or psyllium, may reduce LDL cholesterol by 5–10%. Garlic, soy protein, vitamin C, pecans, and plant sterols may also result in reduction of LDL cholesterol. Because oxidation of LDL cholesterol is a potential initiating event in atherogenesis, diets rich in antioxidants, found primarily in fruits and vegetables, may be helpful (see Chapter 29).

Studies have suggested that when all of these elements are combined into a single dietary prescription, the impact of diet on LDL cholesterol may approach that of statin medications, lowering LDL cholesterol by close to 30%.

**References**

Pharmacologic Therapy

Most patients whose risk from CHD is considered high enough to warrant pharmacologic therapy of an elevated LDL cholesterol should be given aspirin prophylaxis at a dose of 81 mg/d unless there are contraindications such as aspirin sensitivity, bleeding diatheses, or active peptic ulcer disease. The benefit of aspirin in reducing the risk of CHD in men is equivalent to that of cholesterol lowering. Other CHD risk factors, such as hypertension and smoking, should also be controlled.

If the decision to treat a patient with an LDL-lowering drug is made, a goal for treatment is set. The National Cholesterol Education Program's Adult Treatment Panel III (NCEP ATP III) guidelines remain the mainstay of clinical practice. For patients with CHD or CHD risk equivalents, the goal is LDL <100 mg/dL (<2.59 mmol/L), but for patients with very high risk, a goal of LDL <70 mg/dL (<1.81 mmol/L) is a therapeutic option (see Table 28–3). This goal may also be appropriate for patients with very high risk who have a baseline LDL <100 mg/dL (<2.59 mmol/L). For patients with two or more risk factors and a 10-year CHD risk of 10–20%, the recommended goal is LDL <130 mg/dL (<3.36 mmol/L), but a goal of <100 mg/dL (<2.59 mmol/L) is optional. For those with two or more risk factors and a 10-year CHD risk of <10%, the goal is <130 mg/dL (<3.36 mmol/L). For those with zero or one risk factor, the goal is LDL <160 mg/dL (<4.14 mmol/L) (see Table 28–3). In most instances, intensity of therapy should be sufficient to achieve a 30–40% reduction in LDL cholesterol. Once the goal is reached, the lipid profile should be monitored periodically (every 6–12 months), with consideration given to periodic reductions in drug dose.

A. Niacin (Nicotinic Acid)

Niacin was the first lipid-lowering agent that was associated with a reduction in total mortality. Long-term follow-up of a secondary prevention trial of middle-aged men with previous myocardial infarction disclosed that about half of those who had been previously treated with niacin had died, compared with nearly 60% of the placebo group. This favorable effect on mortality was not seen during the trial itself, though there was a reduction in the incidence of recurrent coronary events.

Niacin reduces the production of VLDL particles, with secondary reduction in LDL and increases in HDL cholesterol levels. The average effect of full-dose niacin therapy, 3–4.5 g/d, is a 15–25% reduction in LDL cholesterol and a 25–35% increase in HDL cholesterol. Full doses are required to obtain the LDL effect, but the HDL effect is observed at lower doses, eg, 1 g/d. Niacin will also reduce triglycerides by half and will lower lipoprotein(a) (Lp[a]) levels and will increase plasma homocysteine levels. Intolerance to niacin is common; only 50–60% of patients can take full doses. Niacin causes a prostaglandin-mediated flushing that patients may describe as “hot flashes” or pruritus and that can be decreased with aspirin (81–325 mg/d) or other non-steroidal anti-inflammatory agents taken during the same day. Flushing may also be decreased by initiating niacin therapy with a very small dose, eg, 100 mg with the evening meal. The dose can be doubled each week until 1.5 g/d is tolerated. After rechecking blood lipids, the dose is increased and divided over three meals until the goal of 3–4.5 g/d is reached (eg, 1 g with each meal). Extended-release niacin is better tolerated by most patients. It is not known whether routine monitoring of liver enzymes results in early detection and thus reduced severity of this side effect. Niacin can also exacerbate gout and peptic ulcer disease. Although niacin may increase blood sugar in some patients, clinical trials have shown that niacin can be safely used in diabetic patients.

B. Bile Acid–Binding Resins

The bile acid–binding resins include cholestyramine, colesevelam, and colestipol. Treatment with these agents reduces the incidence of coronary events in middle-aged men by about 20%, with no significant effect on total mortality. The resins work by binding bile acids in the intestine. The resultant reduction in the enterohepatic circulation causes the liver to increase its production of bile acids, using hepatic cholesterol to do so. Thus, hepatic LDL receptor activity increases, with a decline in plasma LDL levels. The triglyceride level tends to increase slightly in some patients treated with bile acid–binding resins; they should be used with caution in those with elevated triglycerides and probably not at all in patients who have triglyceride levels above 500 mg/dL. The clinician can anticipate a reduction of 15–25% in the LDL cholesterol level, with insignificant effects on the HDL level.

The usual dose of cholestyramine is 12–36 g of resin per day in divided doses with meals, mixed in water or, more palatably, juice. Doses of colestipol are 20% higher (each packet contains 5 g of resin). The dose of colesevelam is 625 mg, 6–7 tablets per day.

These agents often cause gastrointestinal symptoms, such as constipation and gas. They may interfere with the absorption of fat-soluble vitamins (thereby complicating the management of patients receiving warfarin) and may bind other drugs in the intestine. Concurrent use of psyllium may ameliorate the gastrointestinal side effects.

C. Hydroxymethylglutaryl-Coenzyme A (HMG-CoA) Reductase Inhibitors (Statins)

The HMG-CoA reductase inhibitors (statins) include atorvastatin, fluvastatin, lovastatin, pitavastatin, pravastatin, rosuvastatin, and simvastatin. These agents work by inhibiting the rate-limiting enzyme in the formation of cholesterol. They reduce myocardial infarctions and total mortality in secondary prevention, as well as in older middle-aged men free of CHD. A meta-analysis has demonstrated significant reduction in risk of stroke. Cholesterol synthesis in the liver is reduced, with a compensatory increase in hepatic LDL receptors (presumably so that the liver can take more of the cholesterol that it needs from the blood) and a reduction in the circulating LDL cholesterol level by up to 35%. There are also modest increases in HDL levels and decreases in triglyceride levels.

Oral doses are as follows: atorvastatin, 10–80 mg/d; fluvastatin, 20–40 mg/d; lovastatin, 10–80 mg/d; pitavastatin...
2–4 mg/d; pravastatin, 10–40 mg/d; rosuvastatin, 5–40 mg/d; and simvastatin, 5–40 mg/d. There is no clear superiority of one HMG-CoA reductase inhibitor over others. These agents are given once daily. The most common side effects are muscle aches, occurring in up to 10% of patients, and mild gastrointestinal effects. More serious, but extremely uncommon, side effects include liver failure and muscle disease including myositis and rhabdomyolysis. Liver disease is more common in patients also taking fibrates or niacin. Muscle disease is more common with statins and fibrates and niacin as well as with erythromycin, antifungal medications, nefazodone, and cyclosporine. Manufacturers of HMG-CoA reductase inhibitors recommend regular monitoring of liver and muscle enzymes.

D. Fibrates

The fibrates are peroxisome proliferative-activated receptor-α (PPAR-α) agonists that result in potent reductions of plasma triglycerides and increases in HDL cholesterol. They reduce LDL levels by about 10–15%, although the result is quite variable, and triglyceride levels by about 40% and raise HDL levels by about 15–20%. The fibric acid derivatives or fibrates approved for use in the United States are gemfibrozil and fenofibrate. Ciprofibrate and bezafibrate are also available for use internationally.

Gemfibrozil reduced CHD rates in hypercholesterolemic middle-aged men free of coronary disease in the Helsinki Heart Study. The effect was observed only among those who also had lower LDL cholesterol levels and high triglyceride levels. In a VA study, gemfibrozil was also shown to reduce cardiovascular events in men with existing CHD whose primary lipid abnormality was a low HDL cholesterol. There was no effect on all-cause mortality.

The usual dose of gemfibrozil is 600 mg once or twice a day. Side effects include cholelithiasis, hepatitis, and myositis. The incidence of the latter two conditions may be higher among patients also taking other lipid-lowering agents. In the largest clinical trial that used clofibrate, there were significantly more deaths—especially due to cancer—in the treatment group; it should not be used.

E. Ezetimibe

Ezetimibe is a lipid-lowering drug that inhibits the intestinal absorption of dietary and biliary cholesterol by blocking passage across the intestinal wall by inhibiting a cholesterol transporter. The usual dose of ezetimibe is 10 mg/d orally. Ezetimibe reduces LDL cholesterol between 15% and 20% when used as monotherapy and can further reduce LDL in patients taking statins who are not yet at therapeutic goal.

However, the effects of ezetimibe on CHD and its long-term safety are not yet known. Results from one small clinical trial, ENHANCE (a study of 720 persons with heterozygous familial hypercholesterolemia), showed no significant difference of intimal media thickness with ezetimibe plus an HMG-CoA reductase inhibitor compared with an HMG-CoA reductase inhibitor alone. A second study compared a statin plus ezetimibe with a statin plus extended-release niacin. The statin plus niacin caused a significant regression of carotid intima-media thickness and was superior to the statin plus ezetimibe combination.

Initial Selection of Medication

At present there are no absolute guidelines for selection of available lipid-modifying medications in particular patients. Nonetheless, clinical trials provide guidance (Table 28–4). For most patients who require a lipid-modifying medication, an HMG-CoA reductase inhibitor is preferred. Although niacin will also have beneficial effects on lipids in both men and women with CHD, there is less evidence demonstrating the desired effects on CHD and all-cause mortality. Resins are the only lipid-modifying medication considered safe in pregnancy.

Combination therapy may be used to meet lipid targets in some patients or to achieve other therapeutic goals. For example, low-dose niacin (0.5–1 g/d), will substantially increase the HDL cholesterol when added to an HMG-CoA reductase inhibitor. Despite improvements in the lipid profile, however, there are few data demonstrating improved clinical outcomes of combination therapy when compared with HMG-CoA reductase inhibitors alone. Combinations may also increase the risk of complications of drug therapy. The combination of gemfibrozil and HMG-CoA reductase inhibitors increases the risk of muscle and liver disease more than either drug alone.

Hsia J et al. Cardiovascular event reduction and adverse events among subjects attaining low-density lipoprotein cholesterol <30 mg/dl with rosuvastatin. The JUPITER trial (Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin). J Am Coll Cardiol. 2011 Apr 19;57(16):1666–75. [PMID: 21492764]

LDL, low-density lipoprotein; HDL, high-density lipoprotein; ±, variable, if any; others, indicates availability of less expensive generic preparations; OTC, over the counter.

Patients with very high levels of serum triglycerides (>1000 mg/dL) are at risk for pancreatitis. The pathophysiology is not certain, since pancreatitis never develops in some patients with very high triglyceride levels. Most patients with congenital abnormalities in triglyceride metabolism present in childhood; hypertriglyceridaemia-induced pancreatitis first presenting in adults is more commonly due to an acquired problem in lipid metabolism.

Although there are no clear triglyceride levels that predict pancreatitis, most clinicians treat fasting levels above 500 mg/dL (5 mmol/L). The risk of pancreatitis may be more related to the triglyceride level following consumption of a fatty meal. Because postprandial increases in triglyceride are inevitable if fat-containing foods are eaten, fasting triglyceride levels in persons prone to pancreatitis should be kept well below that level.

The primary therapy for high triglyceride levels is dietary, avoiding alcohol, simple sugars, refined starches, saturated and trans fatty acids, and restricting total calories. Control of secondary causes of high triglyceride levels (see Table 28–1) may also be helpful. In patients with fasting triglycerides ≥ 500 mg/dL (≥ 5 mmol/L) despite adequate dietary compliance—and certainly in those with a previous episode of pancreatitis—therapy with a triglyceride-lowering drug (eg, niacin, a fibrac...
derivative, omega-3-acid ethyl esters, or an HMG-CoA reductase inhibitor) is indicated. Combinations of these medications may also be used.

Whether patients with elevated triglycerides (>150 mg/dl or 1.5 mmol/L) should be treated to prevent CHD is not known. Meta-analysis of 17 observational studies suggests that after adjustment for other risk factors, elevated triglycerides increased CHD risk in men by 14% and in women by 37%. Triglyceride-rich lipoproteins have been found in human atheromas, and elevated triglycerides are associated with small dense LDL in most instances. Elevated triglycerides are also an important feature of the metabolic syndrome, found in an estimated 25% of Americans—defined by three or more of the following five abnormalities: waist circumference >102 cm in men or >88 cm in women, serum triglyceride level of at least 150 mg/dL, HDL level of <40 mg/dL in men or <50 mg/dL in women, blood pressure of at least 130/85 mm Hg, and serum glucose level of at least 110 mg/dL. Other data, however, suggest that triglyceride measurements do not improve discrimination between those with and without CHD events, and clinical trial data are not available to support the routine treatment of high triglycerides in all patients.

The NCEP ATP III guidelines, however, recommend an aggressive approach to triglyceride management. For those with borderline levels (150–199 mg/dL or 1.5–1.99 mmol/L), emphasis is placed on calorie restriction and exercise. For patients with high triglycerides (>200 mg/dL), the non-HDL cholesterol should be measured (total cholesterol – HDL cholesterol). The ATP III report recommends that non-HDL cholesterol should be treated with diet and medications to result in levels 30 mg/dL higher than the LDL goal. The ATP III report does not differentiate between primary and secondary prevention. It is reasonable to use this approach for patients with CHD and risk equivalents for that disease but not for lower-risk patients.

Protein–energy Malnutrition

**ESSENTIALS OF DIAGNOSIS**

- Decreased intake of energy or protein, increased nutrient losses, or increased nutrient requirements.
- Weight loss and growth failure.
- **Kwashiorkor**: caused by protein deficiency.
- **Marasmus**: caused by combined protein and energy deficiency.
- In severe cases, virtually all organ systems are affected.
- Protein loss correlates with weight loss: 35–40% total body weight loss is usually fatal.

**General Considerations**

Protein–energy malnutrition occurs as a result of a relative or absolute deficiency of energy and protein. It may be primary, due to inadequate food intake, or secondary, as a result of other illness. For most developing nations, primary protein–energy malnutrition remains among the most significant health problems. Protein–energy malnutrition has been described as two distinct syndromes. **Kwashiorkor**, caused by a deficiency of protein in the presence of adequate energy, is typically seen in weaning infants at the birth of a sibling in areas where foods containing protein are insufficiently abundant. **Marasmus**, caused by combined protein and energy deficiency, is most commonly seen where adequate quantities of food are not available.

In industrialized societies, protein–energy malnutrition is most often secondary to other diseases. **Kwashiorkor-like secondary protein–energy malnutrition** occurs primarily in association with hypermetabolic acute illnesses such as trauma, burns, and sepsis. **Marasmus-like secondary protein–energy malnutrition** typically results from chronic diseases such as chronic obstructive pulmonary disease (COPD), congestive heart failure, cancer, or AIDS. These syndromes have been estimated to be present in at least 20% of hospitalized patients. A substantially greater number of patients have risk factors that could result in these syndromes. In both syndromes, protein–energy malnutrition is caused either by decreased intake of energy and protein, increased nutrient losses, or increased nutrient requirements dictated by the underlying illness. For example, diminished oral intake may result from poor dentition or various gastrointestinal disorders. Loss of nutrients results from malabsorption and diarrhea as well as from glycosuria. Nutrient requirements are increased by fever, surgery, neoplasia, and burns.

**Pathophysiology**

Protein–energy malnutrition affects every organ system. The most obvious results are loss of body weight, adipose stores, and skeletal muscle mass. Weight losses of 5–10% are usually tolerated without loss of physiologic function; losses of 35–40% of body weight usually result in death. Loss of protein from skeletal muscle and internal organs is usually proportionate to weight loss. Protein mass is lost from the liver, gastrointestinal tract, kidneys, and heart.

As protein–energy malnutrition progresses, organ dysfunction develops. Hepatic synthesis of serum proteins decreases, and depressed levels of circulating proteins are observed. Cardiac output and contractility are decreased, and the electrocardiogram (ECG) may show decreased voltage and a rightward axis shift. Autopsies of patients who die with severe undernutrition show myofibrillar atrophy and interstitial edema of the heart.

Respiratory function is affected primarily by weakness and atrophy of the muscles of respiration. Vital capacity and tidal volume are depressed, and mucociliary clearance is abnormal. The gastrointestinal tract is affected by mucosal atrophy and loss of villi of small intestine, resulting in malabsorption. Intestinal disaccharidase deficiency and mild pancreatic insufficiency also occur.

Changes in immunologic function are among the most important changes seen in protein–calorie undernutrition. T lymphocyte number and function are depressed. Changes
in B cell function are more variable. Impaired complement activity, granulocyte function, and anatomic barriers to infection are noted, and wound healing is poor.

Clinical Findings

The clinical manifestations of protein–energy malnutrition range from mild growth retardation and weight loss to a number of distinct clinical syndromes. Children in the developing world manifest marasmus and kwashiorkor. In secondary protein–energy malnutrition as seen in industrialized nations, clinical manifestations are affected by the degree of protein and energy deficiency, the underlying illness that resulted in the deficiency, and the patient’s nutritional status prior to illness.

Progressive wasting that begins with weight loss and proceeds to more severe cachexia typically develops in most patients with marasmus-like secondary protein–energy malnutrition. In the most severe form of this disorder, most body fat stores disappear and muscle mass decreases, most noticeably in the temporalis and interosseous muscles. Laboratory studies may be unremarkable—serum albumin, for example, may be normal or slightly decreased, rarely decreasing to < 2.8 g/dL (< 28 g/L). In contrast, owing to its rapidity of onset, kwashiorkor-like secondary protein–energy malnutrition may develop in patients with normal subcutaneous fat and muscle mass or, if the patient is obese, in patients with excess fat and muscle. The serum protein level, however, typically declines and the serum albumin is often < 2.8 g/dL (< 28 g/L). Dependent edema, ascites, or anasarca may develop. As with primary protein–energy malnutrition, combinations of the marasmus-like and kwashiorkor-like syndromes can occur simultaneously, typically in patients with progressive chronic disease in whom a superimposed acute illness develops.

Treatment

The treatment of severe protein–energy malnutrition is a slow process requiring great care. Initial efforts should be directed at correcting fluid and electrolyte abnormalities and infections. Of particular concern are depletion of potassium, magnesium, and calcium and acid–base abnormalities. The second phase of treatment is directed at repletion of protein, energy, and micronutrients. Treatment is started with modest quantities of protein and calories calculated according to the patient’s actual body weight. Adult patients are given 1 g/kg of protein and 30 kcal/kg of calories. Concomitant administration of vitamins and minerals is obligatory. Either the enteral or parenteral route can be used, although the former is preferable. Enteral fat and lactose are withheld initially. Patients with less severe protein–calorie undernutrition can be given calories and protein simultaneously with the correction of fluid and electrolyte abnormalities. Similar quantities of protein and calories are recommended for initial treatment.

Patients treated for protein–energy malnutrition require close follow-up. In adults, both protein and calories are advanced as tolerated, adults to 1.5 g/kg/d of protein and 40 kcal/kg/d of calories.

Patients who are re-fed too rapidly may develop a number of untoward clinical sequelae. During refeeding, circulating potassium, magnesium, phosphorus, and glucose move intracellularly and can result in low serum levels of each. The administration of water and sodium with carbohydrate refeeding can result in congestive heart failure in persons with depressed cardiac function. Enteral refeeding can lead to malabsorption and diarrhea due to abnormalities in the gastrointestinal tract.

Refeeding edema is a benign condition to be differentiated from congestive heart failure. Changes in renal sodium reabsorption and poor skin and blood vessel integrity result in the development of dependent edema without other signs of heart disease. Treatment includes reassurance, elevation of the dependent area, and modest sodium restriction. Diuretics are usually ineffective, may aggravate electrolyte deficiencies, and should not be used.

The prevention and early detection of protein–energy malnutrition in hospitalized patients require awareness of its risk factors and early symptoms and signs. Patients at risk require formal assessment of nutritional status and close observation of dietary intake, body weight, and nutritional requirements during the hospital stay.

Obesity

Excess adipose tissue; body mass index (BMI) > 30.

Upper body obesity (abdomen and flank) of greater health consequence than lower body obesity (buttocks and thighs).

Associated with health consequences, including diabetes mellitus, hypertension, and hyperlipidemia.

General Considerations

Obesity is one of the most common disorders in medical practice and among the most frustrating and difficult to
manage. Little progress has been made in prevention or treatment, yet major changes have occurred in our understanding of its causes and its implications for health.

Definition & Measurement

Obesity is defined as an excess of adipose tissue. Accurate quantification of body fat requires sophisticated techniques not usually available in clinical practice. Physical examination is usually sufficient to detect excess body fat. More quantitative evaluation is performed by calculating the BMI.

The BMI closely correlates with excess adipose tissue. It is calculated by dividing measured body weight in kilograms by the height in meters squared.

The National Institutes of Health (NIH) define a normal BMI as 18.5–24.9. Overweight is defined as BMI = 25–29.9. Class I obesity is 30–34.9, class II obesity is 35–39.9, and class III (extreme) obesity is BMI > 40. Factors other than total weight, however, are also important. Upper body obesity (excess fat around the waist and flank) is a greater health hazard than lower body obesity (fat in the thighs and buttocks). Obese patients with increased abdominal circumference (>102 cm in men and 88 cm in women) or with high waist-hip ratios (>1.0 in men and >0.85 in women) have a greater risk of diabetes mellitus, stroke, coronary artery disease, and early death than equally obese patients with lower ratios. Further differentiation of the location of excess fat suggests that visceral fat within the abdominal cavity is more hazardous to health than subcutaneous fat around the abdomen.

Current U.S. survey data demonstrate that 68% of Americans are overweight and 33.8% are obese. Women in the United States are more apt to be obese than men, and African-American and Mexican-American women are more obese than whites. The poor are more obese than the rich regardless of race.

Health Consequences of Obesity

Obesity is associated with significant increases in both morbidity and mortality. A great many disorders occur with greater frequency in obese people. The most important and common of these are hypertension, type 2 diabetes mellitus, hyperlipidemia, coronary artery disease, degenerative joint disease, and psychosocial disability. Approximately 60% of individuals with obesity in the United States have the metabolic syndrome (including three or more of the following factors: elevated abdominal circumference, blood pressure, blood triglycerides, and fasting blood sugar, and low high-density lipoprotein [HDL] cholesterol). Certain cancers (colon, ovary, and breast), thromboembolic disorders, digestive tract diseases (gallbladder disease, gastroesophageal reflux disease), and skin disorders are also more prevalent in the obese. Surgical and obstetric risks are greater. Obese patients also have a greater risk of pulmonary functional impairment including sleep apnea, endocrine abnormalities, proteinuria, and increased hemoglobin concentration. Patients with obesity have increased rates of major depression and binge eating disorder. Several studies have documented that obese individuals are also subject to various forms of social discrimination.

In young and middle-aged adults, mortality from all causes and mortality from cardiovascular disease increase in proportion to the degree of obesity. The relative risk associated with obesity, however, decreases with age, and weight is no longer a risk factor in adults over age 75 years. Analysis of data from the National Health and Nutrition Examination Survey (NHANES) has suggested that lesser amounts of excess weight (BMI between 25 and 29.9) may not be associated with excess mortality.

Etiology

Until recently, obesity was considered to be the direct result of a sedentary lifestyle plus chronic ingestion of excess calories. Although these factors are undoubtedly the principal cause in many cases, there is evidence for strong genetic influences on the development of obesity. Adopted children demonstrate a close relationship between their BMI and that of their biologic parents. No such relationship is found between the children and their adoptive parents. Twin studies also demonstrate substantial genetic influences on BMI with little influence from the childhood environment. As much as 40–70% of obesity may be explained by genetic influences.

Genetic determinants of some types of obesity have now been established. Five genes affecting control of appetite have been identified in mice. Mutations of each gene result in obesity, and each has a human homolog. One gene codes for a protein expressed by adipose tissue—leptin—and another for the leptin receptor in the brain. The other three genes affect brain pathways downstream from the leptin receptor. Numerous other candidate genes for human obesity have been identified. Only a small percentage (4–6%) of human obesity is thought to be due to single gene mutations. Most human obesity undoubtedly develops from the interactions of multiple genes, environmental factors, and behavior. The rapid increase in obesity in the last several decades clearly points to a major role of environmental factors in the development of obesity.

Medical Evaluation of the Obese Patient

Historical information should be obtained about age at onset, recent weight changes, family history of obesity, occupational history, eating and exercise behavior, cigarette and alcohol use, previous weight loss experience, and psychosocial factors including assessment for depression and eating disorders. Particular attention should be directed at use of laxatives, diuretics, hormones, nutritional supplements, and over-the-counter medications.

Physical examination should assess the BMI, the degree and distribution of body fat, overall nutritional status, and signs of secondary causes of obesity.

Less than 1% of obese patients have an identifiable secondary, nonpsychiatric, cause of obesity. Hypothyroidism and Cushing syndrome are important examples that can usually be diagnosed by physical examination in patients with unexplained recent weight gain. Such patients require
further endocrinologic evaluation, including serum thyroid-stimulating hormone (TSH) determination and dexamethasone suppression testing (see Chapter 26). All obese patients should be assessed for medical consequences of their obesity by screening for the metabolic syndrome. Blood pressure, waist circumference, fasting glucose, low-density lipoprotein (LDL) and HDL cholesterol, and triglycerides should be measured.

**Treatment**

Using conventional dietary techniques, only 20% of patients will lose 20 lb and maintain the loss for over 2 years; 5% will maintain a 40-lb loss. Average weight loss is approximately 7% of baseline weight. Continued close provider–patient contact appears to be more important for success of treatment than the specific features of any given treatment regimen. Careful patient selection will improve success rates and decrease frustration of both patients and therapists. Only sufficiently motivated patients should enter active treatment programs. Specific attempts to identify motivated patients—eg, requesting a 3-day diet record—are often useful.

Most successful programs employ a multidisciplinary approach to weight loss, with hypocaloric diets, behavior modification to change eating behavior, aerobic exercise, and social support. Emphasis must be on maintenance of weight loss.

**Dietary instructions** for most patients incorporate the same principles that apply to healthy people who are not obese. This is achieved by emphasizing intake of a wide variety of predominantly “unprocessed” foods. Special attention is usually paid to limiting foods that provide large amounts of calories without other nutrients, ie, fat, sucrose, and alcohol. There is no physiologic advantage to diets that restrict carbohydrates, advocate relatively larger amounts of protein or fats, or recommend ingestion of foods one at a time. Diets that are restricted in carbohydrates (such as the Atkins and South Beach diets), however, can be effective in achieving a lower total caloric intake. Several studies have demonstrated that low-carbohydrate diets can be used safely and effectively for weight loss without adverse effects on lipids or other metabolic parameters. Meal replacement diets can also be used effectively and safely to achieve weight loss.

Long-term changes in eating behavior are required to maintain weight loss. Although formal behavior modification programs are available to which patients can be referred, the clinician caring for obese patients can teach a number of useful behavioral techniques. The most important technique is to emphasize planning and record keeping. Patients can be taught to plan menus and exercise sessions and to record their actual behavior. Record keeping not only aids in behavioral change, but also helps the provider to make specific suggestions for problem solving. Patients can be taught to recognize “eating cues” (emotional, situational, etc) and how to avoid or control them. Regular self-monitoring of weight is also associated with improved long-term weight maintenance.

**Exercise** offers a number of advantages to patients trying to lose weight and keep it off. Aerobic exercise directly increases the daily energy expenditure and is particularly useful for long-term weight maintenance. Exercise will also preserve lean body mass and partially prevent the decrease in basal energy expenditure (BEE) seen with semistarvation. When compared with no treatment, exercise alone results in small amounts of weight loss. Exercise plus diet results in greater weight loss than diet alone. A greater intensity of exercise is associated with a greater amount of weight loss. Up to 1 hour of moderate exercise per day is associated with long-term weight maintenance in individuals who have successfully lost weight. Social support is essential for a successful weight loss program. Continued close contact with clinicians and involvement of the family and peer group are useful techniques for reinforcing behavioral change and preventing social isolation.

Patients with severe obesity may require more aggressive treatment regimens. Very-low-calorie diets (≤ 800 kcal/d) result in rapid weight loss and marked initial improvement in obesity-related metabolic complications. Patients are commonly maintained on such programs for 4–6 months. Patients who adhere to the program lose an average of 2 lb per week. Average maximum weight loss is approximately 15% of initial weight. Most programs use meal replacement diets to achieve the very-low-calorie intake. Long-term weight maintenance following meal replacement programs is less predictable and requires concurrent behavior modification, long-term use of low-calorie diets, careful self-monitoring, and regular exercise. Side effects such as fatigue, orthostatic hypotension, cold intolerance, and fluid and electrolyte disorders are observed in proportion to the degree of calorie reduction and require regular supervision by a clinician. Other less common complications include gout, gallbladder disease, and cardiac arrhythmias. Although weight loss is more rapidly achieved with very-low-calorie diets as compared with traditional diets, long-term outcomes are equivalent.

**Medications** for the treatment of obesity are available both over the counter and by prescription. Considerable controversy exists as to the appropriate use of medications for obesity. NIH clinical obesity guidelines state that obesity drugs may be used as part of a comprehensive weight loss program for patients with BMI > 30 or those with BMI > 27 with obesity-related risk factors. There are few data, however, to suggest that medications can improve long-term outcomes associated with obesity.

Several medications are approved by the US Food and Drug Administration (FDA) for treatment of obesity. Catecholaminergic medications (eg, phentermine, diethylpropion, mazindol) are approved for short-term use only and have limited utility. Sibutramine, previously approved for the treatment of obesity, was withdrawn from the United States market in 2010 following the publication of a large study demonstrating an increased risk of strokes and myocardial infarctions.

**Orlistat** works in the gastrointestinal tract rather than the central nervous system. By inhibiting intestinal lipase, orlistat reduces fat absorption. As expected, orlistat may result in diarrhea, gas, and cramping and perhaps also reduced absorption of fat-soluble vitamins. In randomized trials with up to 2 years of follow-up, orlistat has resulted in
2–4 kg greater weight loss than placebo. Orlistat (120 mg orally up to three times daily with each fat-containing meal) is the only medication approved for longer-term treatment of obesity in the United States. A lower dose formulation (Alli 60 mg, one capsule orally up to three times daily with each fat-containing meal; maximum of three capsules per day) is available without a prescription. Long-term clinical benefits have not been demonstrated. Although orlistat results in some additional weight loss at the end of 1- and 2-year clinical trials and, in some studies, improved obesity-related metabolic parameters, a beneficial impact on obesity-related clinical outcomes has not been established.

Several new medications and combinations of existing medications are also being investigated, but none have yet been approved for use in the United States. Lorcaserin, a selective serotonin receptor agonist, was not approved by the FDA due to increased mammary adenocarcinoma in animal studies. The combination of phentermine and topiramate was not approved due to excess psychiatric events, increased heart rate, and teratogenicity. Bupropion and naltrexone resulted in short-term weight loss but was not approved due to ongoing concerns of increased cardiovascular risk. Bupropion and zonisamide, exenatide and other incretins, and cetilistat (another pancreatic lipase inhibitor) are all being investigated.

**Bariatric surgery** is an increasingly prevalent treatment option for patients with severe obesity. In the United States, gastric operations are considered the procedures of choice. Most popular is the Roux-en-Y gastric bypass (RYGB). In most centers, the operation can be done laparoscopically. RYGB typically results in substantial amounts of weight loss—over 30% of initial body weight in some studies. Complications occur in up to 40% of persons undergoing RYGB surgery and include peritonitis due to anastomotic leak; abdominal wall hernias; staple line disruption; gallstones; neuropathy; marginal ulcers; stomal stenosis; wound infections; thromboembolic disease; gastrointestinal symptoms; and nutritional deficiencies, including iron, vitamin B12, folate, calcium, and vitamin D. Operative mortality rates within 30 days are nil to 1% in low-risk populations but have been reported to be substantially higher in Medicare beneficiaries. One-year mortality rates have been reported as high as 7.5% in men with Medicare. The surgical volume (the number of cases performed by the surgeon or hospital) has been demonstrated to be an important predictor of outcome. Gastric banding (GB) surgeries are increasing as an alternative procedure. GB results in less dramatic weight loss than RYGB but with fewer short-term complications. Frequent follow-up is required to adjust the gastric band. Longer-term follow-up suggests that both procedures are associated with significant regaining of weight. NIH consensus panel recommendations are to limit obesity surgery to patients with BMIs over 40, or over 35 if obesity-related comorbidities are present. The procedure is cost-effective for patients with severe obesity and most third-party payers cover the procedure in selected patients. Outcomes studies have suggested that bariatric surgery is associated with a significant reduction in deaths at 11-year follow-up. In one prospective study, the number needed to treat to prevent one death in 11 years was 77 operations.

**When to Refer**

Patients with BMI over 40 (or over 35 with obesity-related morbidities) who are interested in considering weight loss surgery.

EATING DISORDERS

ANOREXIA NERVOSA

ESSENTIALS OF DIAGNOSIS

- Disturbance of body image and intense fear of becoming fat.
- Weight loss leading to body weight 15% below expected.
- In females, absence of three consecutive menstrual cycles.

General Considerations

Anorexia nervosa typically begins in the years between adolescence and young adulthood. Ninety percent of patients are females, most from the middle and upper socioeconomic strata. The diagnosis is based on weight loss leading to body weight 15% below expected, a distorted body image, fear of weight gain or of loss of control over food intake and, in females, the absence of at least three consecutive menstrual cycles. Other medical or psychiatric illnesses that can account for anorexia and weight loss must be excluded.

The prevalence of anorexia nervosa is greater than previously suggested. In Rochester, Minnesota, for example, the prevalence per 100,000 population is estimated to be 270 for females and 22 for males. Many other adolescent girls have features of the disorder without the severe weight loss.

The cause of anorexia nervosa is not known. Although multiple endocrinologic abnormalities exist in these patients, most authorities believe they are secondary to malnutrition and not primary disorders. Most experts favor a primary psychiatric origin, but no hypothesis explains all cases. The patient characteristically comes from a family whose members are highly goal and achievement oriented. Interpersonal relationships may be inadequate or destructive. The parents are usually overly directive and concerned with slimmness and physical fitness, and much of the family conversation centers around dietary matters. One theory holds that the patient’s refusal to eat is an attempt to regain control of her body in defiance of parental control. The patient’s unwillingness to inhabit an “adult body” may also represent a rejection of adult responsibilities and the implications of adult interpersonal relationships. Patients are commonly perfectionistic in behavior and exhibit obsessional personality characteristics. Marked depression or anxiety may be present.

Clinical Findings

A. Symptoms and Signs

Patients with anorexia nervosa may exhibit severe emaciation and may complain of cold intolerance or constipation. Amenorrhea is almost always present. Bradycardia, hypotension, and hypothermia may be present in severe cases. Examination demonstrates loss of body fat, dry and scaly skin, and increased lanugo body hair. Parotid enlargement and edema may also occur.

B. Laboratory Findings

Laboratory findings are variable but may include anemia, leukopenia, electrolyte abnormalities, and elevations of blood urea nitrogen (BUN) and serum creatinine. Serum cholesterol levels are often increased. Endocrine abnormalities include depressed levels of luteinizing and follicle-stimulating hormones and impaired response of luteinizing hormone to luteinizing hormone-releasing hormone.

Diagnosis & Differential Diagnosis

The diagnosis can be difficult, since many common social and cultural factors promote and maintain anorexic behavior. The diagnosis depends on identification of the common behavioral features and exclusion of medical disorders that would account for weight loss.

Behavioral features required for the diagnosis include intense fear of becoming obese, disturbance of body image, weight loss of at least 15%, and refusal to exceed a minimal normal weight.

The differential diagnosis includes endocrine and metabolic disorders, such as panhypopituitarism, Addison disease, hyperthyroidism, and diabetes mellitus; gastrointestinal disorders, such as Crohn disease and celiac sprue; chronic infections and cancers, such as tuberculosis and lymphoma; and rare central nervous system disorders, such as hypothalamic tumors.

Treatment

The goal of treatment is restoration of normal body weight and resolution of psychological difficulties. Hospitalization may be necessary. Treatment programs conducted by experienced teams are successful in about two-thirds of cases, restoring normal weight and menstruation. One-half continue to experience difficulties with eating behavior and psychiatric problems. Occasional patients with anorexia develop obesity after treatment. Two to 6% of patients die of the complications of the disorder or commit suicide.

Various treatment methods have been used without clear evidence of superiority of one over another. Supportive care by clinicians and nurses is probably the most important feature of therapy. Structured behavioral therapy, intensive psychotherapy, and family therapy may be tried. A variety of medications including tricyclic antidepressants, selected serotonin reuptake inhibitors (SSRIs), and lithium carbonate are effective in some cases; overall, however, clinical trial results have been disappointing. Patients with severe malnutrition must be hemodynamically stabilized and may require enteral or parenteral feeding. Forced feedings should be
BULIMIA NERVOSA

 Essentials of Diagnosis

- Recurrent inappropriate compensation to prevent weight gain such as self-induced vomiting, laxatives, diuretics, fasting, or excessive exercise.
- Overconcern with weight and body shape.

General Considerations

Bulimia nervosa is the episodic uncontrolled ingestion of large quantities of food followed by recurrent inappropriate compensatory behavior to prevent weight gain such as self-induced vomiting, diuretic or cathartic use, or strict dieting or vigorous exercise.

Like anorexia nervosa, bulimia nervosa is predominantly a disorder of young, white, middle- and upper-class women. It is more difficult to detect than anorexia, and some studies have estimated that the prevalence may be as high as 19% in college-aged women.

Clinical Findings

Patients with bulimia nervosa typically consume large quantities of easily ingested high-calorie foods, usually in secrecy. Some patients may have several such episodes a day for a few days; others report regular and persistent patterns of binge eating. Binging is usually followed by vomiting, cathartics, or diuretics and is usually accompanied by feelings of guilt or depression. Periods of binging may be followed by intervals of self-imposed starvation. Body weights may fluctuate but generally are within 20% of desirable weights.

Some patients with bulimia nervosa also have a cryptic form of anorexia nervosa with significant weight loss and amenorrhea. Family and psychological issues are generally similar to those encountered among patients with anorexia nervosa. Bulimic patients, however, have a higher incidence of premorbid obesity, greater use of cathartics and diuretics, and more impulsive or antisocial behavior. Menstruation is usually preserved.

Medical complications are numerous. Gastric dilatation and pancreatitis have been reported after binges. Vomiting can result in poor dentition, pharyngitis, esophagitis, aspiration, and electrolyte abnormalities. Cathartic and diuretic abuse also cause electrolyte abnormalities or dehydration. Constipation and hemorrhoids are common.

Treatment

Treatment of bulimia nervosa requires supportive care and psychotherapy. Individual, group, family, and behavioral therapy have all been utilized. Antidepressant medications may be helpful. The best results have been with fluoxetine hydrochloride and other SSRIs. Although death from bulimia is rare, the long-term psychiatric prognosis in severe bulimia is worse than that in anorexia nervosa.

When to Refer

All patients with diagnosed bulimia should be co-managed with a psychiatrist.

When to Admit

- Signs of hypovolemia, major electrolyte disorders, and severe protein-energy malnutrition.
- Failure to improve with outpatient management.

- Adolescents and young adults with otherwise unexplained weight loss should be evaluated by a psychiatrist.
- All patients with diagnosed anorexia nervosa should be co-managed with a psychiatrist.

Chapter 29

Disorders of Vitamin Metabolism

Thiamine (B₁) Deficiency

ESSENTIALS OF DIAGNOSIS

- Most common in patients with chronic alcoholism.
- Early symptoms of anorexia, muscle cramps, paresthesias, and irritability.
- Advanced syndromes of high output heart failure (“wet beriberi”), peripheral nerve disorders, and Wernicke-Korsakoff syndrome (“dry beriberi”).

General Considerations

Most thiamine deficiency in the United States is due to alcoholism. Patients with chronic alcoholism may have poor dietary intakes of thiamine and impaired thiamine absorption, metabolism, and storage. Thiamine deficiency is also associated with malabsorption, dialysis, and other causes of chronic protein–calorie undernutrition. Thiamine deficiency can be precipitated in patients with marginal thiamine status with intravenous dextrose solutions.

Clinical Findings

Early manifestations of thiamine deficiency include anorexia, muscle cramps, paresthesias, and irritability. Advanced deficiency primarily affects the cardiovascular system (“wet beriberi”) or the nervous system (“dry beriberi”). Wet beriberi occurs in thiamine deficiency accompanied by severe physical exertion and high carbohydrate intakes. Dry beriberi occurs in thiamine deficiency accompanied by inactivity and low calorie intake.

Wet beriberi is characterized by marked peripheral vasodilation resulting in high-output heart failure with dyspnea, tachycardia, cardiomegaly, and pulmonary and peripheral edema, with warm extremities mimicking cellulitis.

Dry beriberi involves both the peripheral and the central nervous systems. Peripheral nerve involvement is typically a symmetric motor and sensory neuropathy with pain, paresthesias, and loss of reflexes. The legs are affected more than the arms. Central nervous system involvement results in Wernicke–Korsakoff syndrome. Wernicke encephalopathy consists of nystagmus progressing to ophthalmoplegia, truncal ataxia, and confusion. Korsakoff syndrome includes amnesia, confabulation, and impaired learning.

Diagnosis

A variety of biochemical tests are available to assess thiamine deficiency. In most instances, however, the clinical response to empiric thiamine therapy is used to support a diagnosis of thiamine deficiency. The most commonly used biochemical tests measure erythrocyte transketolase activity and urinary thiamine excretion. A transketolase activity coefficient > 15–20% suggests thiamine deficiency.

Treatment

Thiamine deficiency is treated with large parenteral doses of thiamine. Fifty to 100 mg/d is administered intravenously for the first few days, followed by daily oral doses of 5–10 mg/d. All patients should simultaneously receive therapeutic doses of other water-soluble vitamins. Although treatment results in complete resolution in half of patients (one-fourth immediately and another one-fourth over days), the other half obtain only partial resolution or no benefit.

When to Refer

Patients with signs of beriberi or Wernicke-Korsakoff syndrome should be referred to a neurologist.

Thiamine Toxicity

There is no known toxicity of thiamine.

Riboflavin (B₂) Deficiency

Clinical Findings

Riboflavin deficiency almost always occurs in combination with deficiencies of other vitamins. Dietary inadequacy, interactions with a variety of medications, alcoholism, and other causes of protein–calorie undernutrition are the most common causes of riboflavin deficiency.

Manifestations of riboflavin deficiency include cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, weakness, corneal vascularization, and anemia.

Diagnosis

Riboflavin deficiency can be confirmed by measuring the riboflavin-dependent enzyme erythrocyte glutathione reductase. Activity coefficients > 1.2–1.3 are suggestive of riboflavin deficiency. Urinary riboflavin excretion and serum levels of plasma and red cell flavins can also be measured.

Treatment

Riboflavin deficiency is usually treated empirically when the diagnosis is suspected. It is easily treated with foods such as meat, fish, and dairy products or with oral preparations of the vitamin. Administration of 5–15 mg/d until
clinical findings are resolved is usually adequate. Riboflavin can also be given parenterally, but it is poorly soluble in aqueous solutions.

**RIBOFLAVIN TOXICITY**

There is no known toxicity of riboflavin.

**NIACIN DEFICIENCY**

**General Considerations**

Niacin is a generic term for nicotinic acid and other derivatives with similar nutritional activity. Unlike most other vitamins, niacin can be synthesized from the amino acid tryptophan. Niacin is an essential component of the co-enzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are involved in many oxidation-reduction reactions. The major food sources of niacin are protein foods containing tryptophan and numerous cereals, vegetables, and dairy products. Niacin in the form of nicotinic acid is used therapeutically for the treatment of hypercholesterolemia and hypertriglyceridemia. Daily doses of 3–6 g can result in significant reductions in levels of LDL and very-low-density lipoproteins (VLDL) and in elevation of HDL. Niacinamide (the form of niacin usually used to treat niacin deficiency) does not exhibit the lipid-lowering effects of nicotinic acid. Historically, niacin deficiency occurred when corn, which is relatively deficient in both tryptophan and niacin, was the major source of calories. Currently, niacin deficiency is more commonly due to alcoholism and nutrient–drug interactions. Niacin deficiency can also occur in inborn errors of metabolism.

**Clinical Findings**

As with other B vitamins, the early manifestations of niacin deficiency are nonspecific. Common complaints include anorexia, weakness, irritability, mouth soreness, glossitis, stomatitis, and weight loss. More advanced deficiency results in the classic triad of pellagra: dermatitis, diarrhea, and dementia. The dermatitis is symmetric, involving sun-exposed areas. Skin lesions are dark, dry, and scaling. The dementia begins with insomnia, irritability, and apathy and progresses to confusion, memory loss, hallucinations, and psychosis. The diarrhea can be severe and may result in malabsorption due to atrophy of the intestinal villi. Advanced pellagra can result in death.

**Diagnosis**

In early deficiency, diagnosis requires a high index of suspicion and attempts at confirmation of niacin deficiency. Niacin metabolites, particularly N-methylnicotinamide, can be measured in the urine. Low levels suggest niacin deficiency but may also be found in patients with generalized under-nutrition. Serum and red cell levels of NAD and NADP are also low but are similarly nonspecific. In advanced cases, the diagnosis of pellagra can be made on clinical grounds.

**Treatment**

Niacin deficiency can be effectively treated with oral niacin, usually given as nicotinamide. Doses ranging from 10 mg/d to 150 mg/d have been used without difficulty.

**NIACIN TOXICITY**

At the high doses of niacin used to treat hyperlipidemia, side effects are common. These include cutaneous flushing (partially prevented by pretreatment with aspirin, 325 mg/d, and use of extended-release preparations) and gastric irritation. Elevation of liver enzymes, hyperglycemia, and gout are less common untoward effects.

**VITAMIN B₆ DEFICIENCY**

Vitamin B₆ deficiency most commonly occurs as a result of interactions with medications—especially isoniazid, cycloserine, penicillamine, and oral contraceptives—or of alcoholism. A number of inborn errors of metabolism and other pyridoxine-responsive syndromes, particularly pyridoxine-responsive anemia, are not clearly due to vitamin deficiency but commonly respond to high doses of the vitamin. Patients with common variable immunodeficiency may have concomitant vitamin B₆ deficiency.

**Clinical Findings**

Vitamin B₆ deficiency results in a clinical syndrome similar to that seen with deficiencies of other B vitamins, including mouth soreness, glossitis, cheilosis, weakness, and irritability. Severe deficiency can result in peripheral neuropathy, anemia, and seizures. Studies have suggested a potential relationship of low vitamin B₆ levels and a variety of clinical conditions including cardiovascular diseases, inflammatory diseases, and certain cancers.

**Diagnosis**

The diagnosis of vitamin B₆ deficiency can be confirmed by measurement of pyridoxal phosphate in blood. Normal levels are > 50 ng/mL.

**Treatment**

Vitamin B₆ deficiency can be effectively treated with oral vitamin B₆ supplements. Doses of 10–20 mg/d are usually...
adequate, though some patients taking medications that interfere with pyridoxine metabolism may need doses as high as 100 mg/d. Inborn errors of metabolism and the pyridoxine-responsive syndromes often require doses up to 600 mg/d.

Vitamin B₆ should be routinely prescribed for patients receiving medications (such as isoniazid) that interfere with pyridoxine metabolism to prevent vitamin B₆ deficiency. This is particularly true for patients who are more likely to have diets marginally adequate in vitamin B₆, such as the elderly, alcoholic patients, or the urban poor. Clinical trials have shown that vitamin B₆ supplementation, combined with other B vitamins, has no benefit on cardiovascular disease outcomes.

**VITAMIN B₆ TOXICITY**

A sensory neuropathy, at times irreversible, occurs in patients receiving large doses of vitamin B₆. Although most patients have taken 2 g or more per day, some patients have taken only 200 mg/d.

**VITAMIN B₁₂ & FOLATE**

Vitamin B₁₂ (cobalamin) and folate are discussed in Chapter 13.

**VITAMIN C (Ascorbic Acid) DEFICIENCY**

Most cases of vitamin C deficiency seen in the United States are due to dietary inadequacy in the urban poor, the elderly, and patients with chronic alcoholism. Patients with chronic illnesses such as cancer and chronic kidney disease and individuals who smoke cigarettes are also at risk.

Clinical Findings

Early manifestations of vitamin C deficiency are nonspecific and include malaise and weakness. In more advanced stages, the typical features of scurvy develop. Manifestations include perifollicular hemorrhages, perifollicular hyperkeratotic papules, petechiae and purpura, splinter hemorrhages, bleeding gums, hemarthroses, and subperiosteal hemorrhages. Periodontal signs do not occur in edentulous patients. Anemia is common, and wound healing is impaired. The late stages of scurvy are characterized by edema, oliguria, neuropathy, intracerebral hemorrhage, and death.

**Diagnosis**

The diagnosis of advanced scurvy can be made clinically on the basis of the skin lesions in the proper clinical situation. Atraumatic hemarthrosis is also highly suggestive. The diagnosis can be confirmed with decreased plasma ascorbic acid levels, typically below 0.1 mg/dL.

**Treatment**

Adult scurvy can be treated orally with 300–1000 mg of ascorbic acid per day. Improvement typically occurs within days. Clinical trials have shown that supplemental vitamin C has no benefit on cardiovascular disease or cancer outcomes.

**VITAMIN C TOXICITY**

Very large doses of vitamin C can cause gastric irritation, flatulence, or diarrhea. Oxalate kidney stones are of theoretic concern because ascorbic acid is metabolized to oxalate, but stone formation has not been frequently reported. Vitamin C can also confound common diagnostic tests by causing false-negative tests for fecal occult blood and both false-negative and false-positive tests for urine glucose.

**VITAMIN A DEFICIENCY**

Clinical Findings

Vitamin A deficiency is one of the most common vitamin deficiency syndromes, particularly in developing countries. In many such regions, it is the most common cause of blindness. In the United States, vitamin A deficiency is usually due to fat malabsorption syndromes or mineral oil laxative abuse and occurs most commonly in the elderly and urban poor.

Night blindness is the earliest symptom. Dryness of the conjunctiva (xerosis) and the development of small white patches on the conjunctiva (Bitot spots) are early signs. Ulceration and necrosis of the cornea (keratomalacia), perforation, endophthalmitis, and blindness are late manifestations. Xerosis and hyperkeratinization of the skin and loss of taste may also occur.
VITAMIN A TOXICITY

Excess intake of β-carotenes (hypercarotenosis) results in staining of the skin a yellow-orange color but is otherwise benign. Skin changes are most marked on the palms and soles, while the sclera remain white, clearly distinguishing hypercarotenosis from jaundice.

Excessive vitamin A (hypervitaminosis A), on the other hand, can be quite toxic. Chronic toxicity usually occurs after ingestion of daily doses of over 50,000 international units/d for > 3 months. Early manifestations include dry, scaly skin, hair loss, mouth sores, painful hyperostoses, anorexia, and vomiting. More serious findings include hypercalcemia; increased intracranial pressure, with papilledema, headaches, and decreased cognition; and hepatomegaly, occasionally progressing to cirrhosis. Excessive vitamin A has also recently been related to increased risk of hip fracture. Acute toxicity can result from ingestion of massive doses of vitamin A, such as in drug overdoses or consumption of polar bear liver. Manifestations include nausea, vomiting, abdominal pain, headache, papilledema, and lethargy.

The diagnosis can be confirmed by elevations of serum vitamin A levels. The only treatment is withdrawal of vitamin A from the diet. Most symptoms and signs improve rapidly.

VITAMIN D

Vitamin D is discussed in Chapter 26. The major food source of vitamin D is fortified milk, but sunlight on the skin is a prime resource as well.

VITAMIN E TOXICITY

Vitamin E has been thought to be the least toxic of the fat-soluble vitamins. Large doses—many times the recommended daily requirement—have been taken for extended periods of time without apparent harm, though nausea, flatulence, and diarrhea have been reported. Clinical trials, however, have suggested an increase in all-cause mortality with high dose (≥ 400 international units/d) vitamin E supplements. Large doses of vitamin E can also increase the vitamin K requirement and can result in bleeding in patients taking oral anticoagulants.
VITAMIN K

Vitamin K is discussed in Chapter 14. Vitamin K is synthesized by intestinal bacteria.

DIET THERAPY

Specific therapeutic diets can be designed to facilitate the medical management of most common illnesses. In most cases, consultation with a registered dietitian is necessary in order to design and implement major dietary changes. Clinicians should be familiar with the indications for special diets and their basic composition to facilitate patient referrals and to maximize patient compliance. Diet therapy is a difficult process, and not all patients are able to cooperate fully. Requesting the patient to record dietary intake for 3–5 days may provide useful insight into the patient’s motivation as well as providing nutrient information about the current diet.

Therapeutic diets can be divided into three groups: (1) diets that alter the consistency of food, (2) diets that restrict or otherwise modify dietary components, and (3) diets that supplement dietary components.

DIETS THAT ALTER CONSISTENCY

► Clear Liquid Diet

This diet provides adequate water, 500–1000 kcal as simple sugar, and some electrolytes. It is fiber free and requires minimal digestion or intestinal motility.

A clear liquid diet is useful for patients with resolving postoperative ileus, acute gastroenteritis, partial intestinal obstruction, and as preparation for diagnostic gastrointestinal procedures. It is commonly used as the first diet for patients who have been taking nothing by mouth for long periods. Because of the low calorie and minimal protein content of the clear liquid diet, it is used only for short periods.

► Full Liquid Diet

The full liquid diet provides adequate water and can be designed to provide adequate calories and protein. Vitamins and minerals—especially folic acid, iron, and vitamin B 
 —may be inadequate and should be provided in the form of supplements. Dairy products, soups, eggs, and soft cereals are used to supplement clear liquids. Commercial oral supplements can also be incorporated into the diet or used alone.

This diet is low in residue and can be used in many instances instead of the clear liquid diet described above—especially in patients with difficulty in chewing or swallowing, with partial obstructions, or in preparation for some diagnostic procedures. Full liquid diets are commonly used following clear liquid diets to advance diets in patients who have been taking nothing by mouth for long periods.

► Soft Diets

Soft diets are designed for patients unable to chew or swallow hard or coarse food. Tender foods are used, and most raw fruits and vegetables and coarse breads and cereals are eliminated. Soft diets are commonly used to assist in progression from full liquid diets to regular diets in postoperative patients, in patients who are too weak or those whose dentition is too poor to handle a general diet, in head and neck surgical patients, in patients with esophageal strictures, and in other patients who have difficulty with chewing or swallowing.

The soft diet can be designed to meet all nutritional requirements.

DIETS THAT RESTRICT NUTRIENTS

Diet can be designed to restrict (or eliminate) virtually any nutrient or food component. The most commonly used restricted diets are those that limit sodium, fat, and protein. Other restrictive diets include gluten restriction in sprue, potassium and phosphate reduction in chronic kidney disease, and various elimination diets for food allergies.

► Sodium-Restricted Diets

Low-sodium diets are useful in the management of hypertension and in conditions in which sodium retention and edema are prominent features, particularly congestive heart failure, chronic liver disease, and chronic kidney disease. Sodium restriction is beneficial with or without diuretic therapy. When used in conjunction with diuretics, sodium restriction allows lower dosage of the diuretic medication and may prevent side effects. Potassium excretion, in particular, is directly related to distal renal tubule sodium delivery, and sodium restriction will decrease diuretic-related potassium losses.

Typical American diets contain a minimum of 4–6 g (175–260 mEq) of sodium per day. A no-added-salt diet contains approximately 3 g (132 mEq) of sodium per day. Further restriction can be achieved with sodium diets of 2 or 1 g/d. Diets with more severe restriction are poorly accepted by patients and are rarely used.

Dietary sodium includes sodium naturally occurring in foods, sodium added during food processing, and sodium added by the consumer during cooking and at the table. About a third of current dietary intake is derived from each. Diets that allow 2000 mg of sodium daily are easiest to design and implement. Such diets generally eliminate added salt, most processed foods, and selected foods with particularly high sodium content. Patients who follow such diets for 2–3 months lose their craving for salty foods and can often continue to restrict their sodium intake indefinitely. Many patients with mild hypertension will achieve significant reductions in blood pressure (approximately 5 mm Hg diastolic) with this degree of sodium restriction. Other patients require more severe sodium restriction (approximately 1000 mg of sodium per day) for reduction in blood pressure.

Diet allowing 1000 mg of sodium require further restriction of commonly eaten foods. Special “low-sodium” products are now available to facilitate such diets. These diets are difficult for most people to follow and are generally reserved for hospitalized patients and highly motivated outpatients—most commonly those with severe liver disease and ascites.
Fat-Restricted Diets

Traditional fat-restricted diets are useful in the treatment of fat malabsorption syndromes. Such diets will improve the symptoms of diarrhea with steatorrhea independently of the primary physiologic abnormality by limiting the quantity of fatty acids that reach the colon. The degree of fat restriction necessary to control symptoms must be individualized. Patients with severe malabsorption can be limited to 40–60 g of fat per day. Diets containing 60–80 g of fat per day can be designed for patients with less severe abnormalities.

In general, fat-restricted diets require broiling, baking, or boiling meat and fish; discarding the skin of poultry and fish and using those foods as the main protein source; using nonfat dairy products; and avoiding desserts, sauces, and gravies.

Low-Cholesterol, Low-Saturated-Fat Diets

Fat-restricted diets that specifically restrict saturated fats and dietary cholesterol are the mainstay of dietary treatment of hyperlipidemia (see Chapter 28). Similar diets are recommended also for diabetes mellitus (see Chapter 27) and for the prevention of coronary artery disease (see Chapter 10). Current recommendations for the prevention of cancer by dietary modification also include fat restriction. The large Women’s Health Initiative Dietary Modification Trial, however, did not show any significant benefit of a low-fat diet on weight control or prevention of cardiovascular disease or cancer.

The aim of these diets is to restrict total fat to < 30% of calories and to achieve a normal body weight by caloric restriction and increased physical activity. Saturated fat is restricted to 7% of calories and dietary cholesterol to 200 mg/d. Saturated fat can be replaced either with complex carbohydrates or, if energy balance permits, with monounsaturated fats. Saturated fat, total fat, and dietary cholesterol can be restricted further, but studies suggest that more extreme restriction offers little further advantage in overall modification of serum lipids. Cholesterol-lowering diets can be further augmented with the addition of plant stanols and sterols and with soluble dietary fiber.

Protein-Restricted Diets

Protein-restricted diets are most commonly used in patients with hepatic encephalopathy due to chronic liver disease and in patients with advanced chronic kidney disease to slow the progression of early disease and to decrease symptoms of uremia in more severe disease. Patients with selected inborn errors of amino acid metabolism and other abnormalities resulting in hyperammonemia also require restriction of protein or of specific amino acids.

Protein restriction is intended to limit the production of nitrogenous waste products. Energy intake must be adequate to facilitate the efficient use of dietary protein. Proteins must be of high biologic value and be provided in sufficient quantity to meet minimal requirements. For most patients, the diet should contain at least 0.6 g/kg/d of protein. Patients with encephalopathy who do not respond to this degree of restriction are unlikely to respond to more severe restriction.

Diets That Supplement Nutrients

High-Fiber Diet

Dietary fiber is a diverse group of plant constituents that is resistant to digestion by the human digestive tract. Typical American diets contain about 5–10 g of dietary fiber per day. Epidemiologic evidence has suggested that populations consuming greater quantities of fiber have a lower incidence of certain gastrointestinal disorders, including diverticulitis and colon cancer. Most authorities currently recommend higher intakes of dietary fiber for health maintenance.

Diets high in dietary fiber (20–35 g/d) are also commonly used in the management of a variety of gastrointestinal disorders, particularly irritable bowel syndrome and recurrent diverticulitis. Diets high in fiber may also be useful to reduce blood sugar in patients with diabetes and to reduce cholesterol levels in patients with hypercholesterolemia. Such diets include greater intakes of fresh fruits and vegetables, whole grains, legumes and seeds, and bran products. For some patients, the addition of psyllium seed (2 tsp per day) or natural bran (one-half cup per day) may be preferable.

High-Potassium Diets

Potassium-supplemented diets are used most commonly to compensate for potassium losses caused by diuretics. Although potassium losses can be partially prevented by using lower doses of diuretics, concurrent sodium restriction, and potassium-sparing diuretics, some patients require additional potassium to prevent hypokalemia. High-potassium diets may also have a direct antihypertensive effect. Typical American diets contain about 3 g (80 mEq) of potassium per day. High-potassium diets commonly contain 4.5–7 g (120–180 mEq) of potassium per day.

Most fruits, vegetables, and their juices contain high concentrations of potassium. Supplemental potassium can also be provided with potassium-containing salt substitutes (up to 20 mEq in one-quarter tsp) or as potassium chloride in solution or capsules, but this is rarely necessary if the above measures are followed to prevent potassium losses and supplement dietary potassium.

High-Calcium Diets

Additional intakes of dietary calcium have been recommended for the prevention of postmenopausal osteoporosis, the prevention and treatment of hypertension, and the prevention of colon cancer. The Women’s Health Initiative, however, suggested that calcium and vitamin D supplementation did not prevent fractures or colon cancer. Nonetheless, many authorities recommend intakes of 1 g of calcium per day for most adults and 1.5 g/d for postmenopausal women. Average American daily intakes are approximately 700 mg/d.
Dairy products are the primary dietary sources of calcium in the United States. Patients with lactose intolerance who cannot tolerate liquid dairy products may be able to use lactose-free milk, take supplemental lactase enzyme supplements, or tolerate nonliquid products such as cheese and yogurt. Leafy green vegetables and canned fish with bones also contain high concentrations of calcium, although the latter is also high in sodium.

**NUTRITIONAL SUPPORT**

Nutritional support is the provision of nutrients to patients who cannot meet their nutritional requirements by eating standard diets. Nutrients may be delivered enterally, using oral nutritional supplements, nasogastric and nasoduodenal feeding tubes, and tube enterostomies, or parenterally, using lines or catheters placed in peripheral or central veins, respectively. Current nutritional support techniques permit adequate nutrient delivery to most patients. Nutrition support should be utilized, however, only if it is likely to improve the patient’s clinical outcome. The financial costs and risks of side effects must be balanced against the potential advantages of improved nutritional status in each clinical situation.

**INDICATIONS FOR NUTRITIONAL SUPPORT**

The precise indications for nutritional support remain controversial. Most authorities agree that nutritional support is indicated for at least four groups of adult patients: (1) those with inadequate bowel syndromes, (2) those with severe prolonged hypercatabolic states (eg, due to extensive burns, multiple trauma, mechanical ventilation), (3) those requiring prolonged therapeutic bowel rest, and (4) those with severe protein–calorie undernutrition with a treatable disease who have sustained a loss of over 25% of body weight.

It has been difficult to prove the efficacy of nutritional support in the treatment of most other conditions. In most cases it has not been possible to show a clear advantage of treatment by means of nutritional support over treatment without such support.

The American Society for Parenteral and Enteral Nutrition (ASPEN) has published recommendations for the rational use of nutritional support. The recommendations emphasize the need to individualize the decision to begin nutritional support, weighing the risks and costs against the benefits to each patient. They also reinforce the need to identify high-risk malnourished patients by nutritional assessment.

**NUTRITIONAL SUPPORT METHODS**

Selection of the most appropriate nutritional support method involves consideration of gastrointestinal function, the anticipated duration of nutritional support, and the ability of each method to meet the patient’s nutritional requirements. The method chosen should meet the patient’s nutritional needs with the lowest risk and lowest cost possible. For most patients, enteral feeding is safer and cheaper and offers significant physiologic advantages. An algorithm for selection of the most appropriate nutritional support method is presented in Figure 29–1.

Prior to initiating specialized enteral nutritional support, efforts should be made to supplement food intake. Attention to patient preferences, timing of meals and diagnostic procedures and use of medications, and the use of foods brought to the hospital by family and friends can often increase oral intake. Patients unable to eat enough at regular mealtimes to meet nutritional requirements can be given oral supplements as snacks or to replace low-calorie beverages. Oral supplements of differing nutritional composition are available for the purpose of individualizing the diet in accordance with specific clinical requirements. Fiber and lactose content, caloric density, protein level, amino acid profiles, vitamin K, and calcium can all be modified as necessary.

Patients unable to take adequate oral nutrients who have functioning gastrointestinal tracts and who meet the criteria for nutritional support are candidates for tube feedings. Small-bore feeding tubes are placed via the nose and nasoduodenal feeding tubes are placed via the nose. Small-bore feeding tubes are placed by means of nasogastric or nasoduodenal feeding tubes. Feeding tubes can usually be passed into the duodenum by leaving an extra length of tubing in the stomach and placing the patient in the right decubitus position. Metoclopramide, 10 mg intravenously, can be given 20 minutes prior to insertion and continued every 6 hours thereafter to facilitate passage through the pylorus.
Occasionally patients will require fluoroscopic or endoscopic guidance to insert the tube distal to the pylorus. Placement of nasogastric and, particularly, nasoduodenal tubes should be confirmed radiographically before delivery of feeding solutions.

Feeding tubes can also be placed directly into the gastrointestinal tract using tube enterostomies. Most tube enterostomies are placed in patients who require long-term enteral nutritional support. Gastrostomies have the advantage of allowing bolus feedings, while jejunostomies require continuous infusions. Gastrostomies—like nasogastric feeding—should be used only in patients at low risk for aspiration. Gastrostomies can also be placed percutaneously with the aid of endoscopy. These tubes can then be advanced to jejunostomies. Tube enterostomies can also be placed surgically.

Patients who require nutritional support but whose gastrointestinal tracts are nonfunctional should receive parenteral nutritional support. Most patients receive parenteral feedings via a central vein—most commonly the subclavian vein. Peripheral veins can be used in some patients, but because of the high osmolality of parenteral solutions this is rarely tolerated for more than a few weeks.

Peripheral vein nutritional support is most commonly used in patients with nonfunctioning gastrointestinal tracts who require immediate support but whose clinical status is expected to improve within 1–2 weeks, allowing enteral feeding. Peripheral vein nutritional support is administered via standard intravenous lines. Solutions should always include lipid and dextrose in combination with amino acids to provide adequate nonprotein calories. Serious side effects are infrequent, but there is a high incidence of phlebitis and infiltration of intravenous lines.

Central vein nutritional support is delivered via intravenous catheters placed percutaneously using aseptic technique. Proper placement in the superior vena cava is documented radiographically before the solution is infused. Catheters must be carefully maintained by experienced nursing personnel and used solely for nutritional support to prevent infection and other catheter-related complications.

### Nutritional Requirements

Each patient’s nutritional requirements should be determined independently of the method of nutritional support. In most situations, solutions of equal nutrient value can be designed for delivery via enteral and parenteral routes, but differences in absorption must be considered. A complete nutritional support solution must contain water, energy, amino acids, electrolytes, vitamins, minerals, and essential fatty acids.

#### Water

For most patients, water requirements can be calculated by allowing 1500 mL for the first 20 kg of body weight plus 20 mL for every kilogram over 20. Additional losses should be replaced as they occur. For average-sized adult patients, fluid needs are about 30–35 mL/kg, or approximately 1 mL/kcal of energy required (see below).

#### Energy

Energy requirements can be estimated by one of three methods: (1) by using standard equations to calculate BEE plus additional calories for activity and illness, (2) by applying a simple calculation based on calories per kilogram of body weight, or (3) by measuring energy expenditure with indirect calorimetry.

BEE can be estimated by the Harris–Benedict equation: for men, $\text{BEE} = 666 + (13.7 \times \text{weight in kg}) + (5 \times \text{height in cm}) – (6.8 \times \text{age in years})$. For women, $\text{BEE} = 655 + (9.5 \times \text{weight in kg}) + (1.8 \times \text{height in cm}) – (4.7 \times \text{age in years})$. For undernourished patients, actual body weight should be used; for obese patients, ideal body weight should be used. For most patients, an additional 20–50% of BEE is administered as nonprotein calories to accommodate energy expenditures during activity or relating to the illness. Occasional patients are noted to have energy expenditures > 150% of BEE.
Energy requirements can be estimated also by multiplying actual body weight in kilograms (for obese patients, ideal body weight) by 30–35 kcal.

Both of these methods provide imprecise estimates of actual energy expenditures, especially for the markedly underweight, overweight, and critically ill patient. Studies using indirect calorimetry have demonstrated that as many as 30–40% of patients will have measured expenditures 10% above or below estimated values. For accurate determination of energy expenditure, indirect calorimetry should be used.

**Electrolytes & Minerals**

Requirements for sodium, potassium, and chloride vary widely. Most patients require 45–145 mEq/d of each. The actual requirement in individual patients will depend on the patient's cardiovascular, renal, endocrine, and gastrointestinal status as well as measurements of serum concentration.

Patients receiving enteral nutritional support should receive adequate vitamins and minerals according to the recommended daily allowances. Most premixed enteral solutions provide adequate vitamins and minerals as long as adequate calories are administered.

Patients receiving parenteral nutritional support require smaller amounts of minerals: calcium, 10–15 mEq/d; phosphorus, 15–20 mEq per 1000 nonprotein calories; and magnesium, 16–24 mEq/d. Most patients receiving nutritional support do not require supplemental iron because body stores are adequate. Iron nutrition should be monitored closely by following the hemoglobin concentration, mean corpuscular volume, and iron studies. Parenteral administration of iron is associated with a number of adverse effects and should be reserved for iron-deficient patients unable to take oral iron.

Patients receiving parenteral nutritional support should be given the trace elements zinc (about 5 mg/d) and copper (about 2 mg/d). Patients with diarrhea will require additional zinc to replace fecal losses. Additional trace elements—especially chromium, manganese, and selenium—are provided to patients receiving long-term parenteral nutrition.

Parenteral vitamins are provided daily. Standardized multivitamin solutions are currently available to provide adequate quantities of vitamins A, B₁₂, C, D, E, thiamine, riboflavin, niacin, pantothenic acid, pyridoxine, folic acid, and biotin. Vitamin K is not given routinely but administered when the prothrombin time becomes abnormal.

**Protein**

Protein and energy requirements are closely related. If adequate calories are provided, most patients can be given 0.8–1.2 g of protein per kilogram per day. Patients undergoing moderate to severe stress should receive up to 1.5 g/kg/d. As in the case of energy requirements, actual weights should be used for normal and underweight patients and ideal weights for patients with significant obesity.

Patients who are receiving protein without adequate calories will catabolize protein for energy rather than utilizing it for protein synthesis. Thus, when energy intake is low, excess protein is needed for nitrogen balance. If both energy and protein intakes are low, extra energy will have a more significant positive effect on nitrogen balance than extra protein.

**Essential Fatty Acids**

Patients receiving nutritional support should be given 2–4% of their total calories as linoleic acid to prevent essential fatty acid deficiency. Most prepared enteral solutions contain adequate linoleic acid. Patients receiving parenteral nutrition should be given at least 250 mL of a 20% intravenous fat (emulsified soybean or safflower oil) about two or three times a week. Intravenous fat can also be used as an energy source in place of dextrose.

**ENTERAL NUTRITIONAL SUPPORT SOLUTIONS**

Most patients who require enteral nutritional support can be given commercially prepared enteral solutions (Table 29–1). Nutritionally complete solutions have been designed to provide adequate proportions of water, energy,

Minerals (eg, Nutrisource Minerals) 

Iso/nosotonic.
protein, and micronutrients. Nutritional incomplete solutions are also available to provide specific macronutrients (eg, protein, carbohydrate, and fat) to supplement complete solutions for patients with unusual requirements or to design solutions that are not available commercially.

Nutritional complete solutions are characterized as follows: (1) by osmolality (isotonic or hypertonic), (2) by lactose content (present or absent), (3) by the molecular form of the protein component (intact proteins; peptides or amino acids), (4) by the quantity of protein and calories provided, and (5) by fiber content (present or absent). For most patients, isotonic solutions containing no lactose or fiber are preferable. Such solutions generally contain moderate amounts of fat and intact protein. Most commercial isotonic solutions contain 1000 kcal and about 37–45 g of protein per liter.

Solutions containing hydrolyzed proteins or crystalline amino acids and with no significant fat content are called elemental solutions, since macronutrients are provided in their most “elemental” form. These solutions have been designed for patients with malabsorption, particularly pancreatic insufficiency and limited fat absorption. Elemental diets are extremely hypertonic and often result in more severe diarrhea. Their use should be limited to patients who cannot tolerate isotonic solutions.

Although formulas have been designed for specific clinical situations—solutions containing primarily essential amino acids (for advanced chronic kidney disease), medium-chain triglycerides (for fat malabsorption), more fat (for respiratory failure and CO₂ retention), and more branched-chain amino acids (for hepatic encephalopathy and severe trauma)—they have not been shown to be superior to standard formulas for most patients. Minor complications of tube feedings occur in 10–15% of patients. Gastrointestinal complications include diarrhea (most common), inadequate gastric emptying, emesis, esophagitis, and occasionally gastrointestinal bleeding. Diarrhea associated with tube feeding may be due to intolerance to the osmotic load or to one of the macronutrients (eg, fat, lactose) in the solution. Patients being fed in this way may also have diarrhea from other causes (as side effects of antibiotics or other drugs, associated with infection, etc), and these possibilities should always be investigated in appropriate circumstances.

Mechanical complications of tube feedings are potentially the most serious. Of particular importance is aspiration. All patients receiving nasogastric tube feedings are at risk for this life-threatening complication. Limiting nasogastric feedings to those patients who can adequately protect their airway and careful monitoring of patients being fed by tube should limit these serious complications to 1–2% of cases. Minor mechanical complications are common and include tube obstruction and dislodgment.

Metabolic complications during enteral nutritional support are common but in most cases are easily managed. The most important problem is hypernatremic dehydration, most commonly seen in elderly patients given excessive protein intake who are unable to respond to thirst. Abnormalities of potassium, glucose, CO₂ production, and acid–base balance may also occur.

**PARENTERAL NUTRITIONAL SUPPORT SOLUTIONS**

Parenteral nutritional support solutions can be designed to deliver adequate nutrients to most patients. The basic parenteral solution is composed of dextrose, amino acids, and water. Electrolytes, minerals, trace elements, vitamins, and medications can also be added. Most commercial solutions contain the monohydrate form of dextrose that provides 3.4 kcal/g. Crystalline amino acids are available in a variety of concentrations, so that a broad range of solutions can be made up that will contain specific amounts of dextrose and amino acids as required.

Typical solutions for central vein nutritional support contain 25–35% dextrose and 2.75–6% amino acids depending upon the patient’s estimated nutrient and water requirements. These solutions typically have osmolalities in excess of 1800 mosm/L and require infusion into a central vein. A typical formula for patients without organ failure is shown in Table 29–2.

**COMPLICATIONS OF ENTERAL NUTRITIONAL SUPPORT**

Minor complications of tube feedings occur in 10–15% of patients. Gastrointestinal complications include diarrhea (most common), inadequate gastric emptying, emesis, esophagitis, and occasionally gastrointestinal bleeding. Diarrhea associated with tube feeding may be due to intolerance to the osmotic load or to one of the macronutrients (eg, fat, lactose) in the solution. Patients being fed in this way may also have diarrhea from other causes (as side effects of antibiotics or other drugs, associated with infection, etc), and these possibilities should always be investigated in appropriate circumstances.

Mechanical complications of tube feedings are potentially the most serious. Of particular importance is aspiration. All patients receiving nasogastric tube feedings are at risk for this life-threatening complication. Limiting nasogastric feedings to those patients who can adequately protect their airway and careful monitoring of patients being fed by tube should limit these serious complications to
Solutions with lower osmolalities can also be designed for infusion into peripheral veins. Typical solutions for peripheral infusion contain 5–10% dextrose and 2.75–4.25% amino acids. These solutions have osmolalities between 800 and 1200 mosm/L and result in a high incidence of thrombophlebitis and line infiltration. These solutions will provide adequate protein for most patients but inadequate energy. Additional energy must be provided in the form of emulsified soybean or safflower oil. Such intravenous fat solutions are currently available in 10% and 25% solutions providing 1.1 and 2.2 kcal/mL, respectively. Intravenous fat solutions are isosmotic and well tolerated by peripheral veins.

Typical patients are given 200–500 mL of a 20% solution each day. As much as 60% of total calories can be administered in this manner.
